Dr. Caldwell Smith was born at Uddingston, Lanarkshire, in 1858, the son of the late Mr. James Smith, LL.D., J.P. He was educated at Glasgow University, where he took the degrees of M.A. in 1878, M.B., C.M. (with commendation) in 1881, and M.D. in 1884, and in 1888 he took the D.P.H. Camb. He started practice in Motherwell, Lanarkshire, and was lecturer in public health in Anderson's College, Glasgow, from 1890 to 1893. He afterwards proceeded to Wandsworth, being appointed medical officer of health of the parish in 1894. He remained in private practice until 1901, when he was appointed full-time medical officer of health of the borough of Wandsworth. To Dr. Caldwell Smith Wandsworth owes many sanitary improvements of which it stood sadly in need. He interested himself specially in the abolition of slum areas and in the prevention and cure of tuberculosis. During his term of office the infant mortality rates were lowered in a marked degree. In 1901 the infant death-rate was 133 per 1000, while 20 years later it dropped to 67 per 1000. Dr. Caldwell Smith joined the Territorial Force soon after its inception, and was appointed Captain to the 2nd London Sanitary Company in 1909, shortly afterwards taking command of the company with the rank of Major. He was mobilised in August, 1914, and later acted as Medical Inspector of Recruits, Territorial Forces, London District. He became Lieutenant-Colonel in 1915, and was President of the Travelling Medical Board, London Division, from 1916 to 1918. In recognition of his military services he was twice mentioned in despatches and received the decoration of C.B.E. (military). He was the author of numerous contributions to the medical press on public health subjects, and was for a time editor of the *Sanitary Journal*. In recent years he had taken great interest in maternity and child welfare work in Wandsworth, and particularly in the Wandsworth War Memorial Maternity Home, which represented his most recent achievement. He was a past president of the metropolitan branch of the Society of Medical Officers of Health.

Dr. Caldwell Smith had held his office at Wandsworth for 22 years, and was expecting to retire in the course of the present year. He was seized suddenly with cerebral hæmorrhage while travelling from his office after his ordinary morning's work, and was taken to the West London Hospital where he died after 12 hours without regaining consciousness. The funeral took place on Feb. 27th at the Putney Vale Cemetery after a service at St. John's Church, Putney, and was attended by the Mayor of Wandsworth, representatives of the corporation and officials, local medical men, and representatives of the Society of Medical Officers of Health, and the Public Health Department of the London County Council.

Dr. Caldwell Smith married Ina, daughter of Mr. J. S. Macdonald, J.P., and of their two sons, the younger, Dr. E. L. Caldwell-Smith, is in practice in London.

THE LATE DR. L. D. H. RUSSELL.—Logan Dillon Hooper Russell, who died on Feb. 13th at the age of 72, received his medical education at University College, London, and qualified in 1870 with the M.R.C.S. Eng. He then went abroad, and after travelling for several years returned to England and took the F.R.C.S. Edin. Again leaving England he went to Canada and the United States, and in 1884 obtained the M.D. Vermont. Part of his time was spent in the West Indies, where he acted as a justice of the peace. He had also been medical officer of health for the Port of Bonny, West Africa, and chief surgeon to the native forces there. On his return to this country he held several important hospital appointments and subsequently settled in practice in Liverpool.

THE LATE DR. IAN DALRYMPLE CLARK HOWDEN.—Dr. Ian Howden, consulting surgeon and radiologist to the Royal Victoria Hospital, Dover, whose death has been recently announced, was a well-known and popular practitioner, connected with Dover for over 26 years. Receiving his medical education at St. Bartholomew's Hospital and at the University of Edinburgh, he graduated M.B., C.M. in 1895, proceeded to the M.D. degree two years later, and took the F.R.C.S. Edin. in 1908. During the war he served first in France in the R.A.M.C., and afterwards, with the rank of lieutenant-commander, R.N.V.R., directed the search-light service in Dover. He was lecturer in physiology to the Technical School, Dover, hon. surgeon to the Dover Ambulance Brigade, and medical officer to Dover College, as well as a member of the Kent County Council. His devotion to duty and kindly nature endeared him to a wide circle of friends and patients.

DEATHS AFTER OPERATIONS.

To the Editor of THE LANCET.

SIR,—The custom of holding coroner's inquests upon patients who have died on the table while under anæsthetics does not in any way add to the safety of the public, and frequently inflicts grave injustice upon the practitioner concerned. This is surely bad enough, but a development has now arisen which bids fair to make the task of the anæsthetist more trying and thankless than ever. In the daily press recently there were reports of an inquest held in London upon a child, who had died from "delayed chloroform poisoning," and we read that the coroner suggested to the anæsthetist that his judgment had been at fault in selecting chloroform in a toxic case.

It is difficult to foresee where this kind of inquisition is going to end. If it is considered necessary to hold inquests on patients who die several days after an operation, why limit it to any particular type of complication? Why not hold inquests upon all such cases of death and let the coroner summon the surgeon to justify his methods and technique? Could anything be more absurd than to hold a public inquiry into a death from acidosis, and accept a death certificate for an equally accidental complication such as pulmonary embolism? If a patient dies of septic poisoning the practitioner in attendance is not summoned to explain why he administered this or that kind of vaccine, and it is preposterous that anæsthetists should be called upon to justify their choice of drug or method of administration to a court composed of people entirely ignorant of the subject; the public who read these reports in the daily papers do not appreciate the fact that the coroner's knowledge of the subject is quite superficial, and they naturally assume, if he questions the anæsthetist's judgment, that the latter is in some degree to be blamed.

In every other branch of practice it is rightly recognised by the legislature that the doctor has done his utmost to save his patient's life—why then should any distinction be made because death has occurred after the administration of an anæsthetic? In his recently published book on anæsthetics Dr. J. Blomfield quotes Mr. Justice Walton as having said: "The science of surgery would soon relapse into a retrograde condition if surgeons were called upon to justify in public every detail of their operation; but it would appear that at present coroners think it their duty to put upon the rack of publicity only the unhappy anæsthetist." How much worse will be the lot of the "unhappy anæsthetist" if this inquisition is to be extended to fatalities which occur some time after the operation!

If, as Sir Bernard Spilsbury is reported to have stated at this inquest, the subject of deaths under anæsthetics is under the consideration of the Ministry of Health, it would seem to be a very favourable opportunity for the medical profession to endeavour to bring about a change in the present arrangements, which create alarm in the public mind, and are grossly unfair to anæsthetists.

I am, Sir, yours faithfully,
J. HENRY CHALDECOTT,
Feb. 28th. Senior Anæsthetist to St. Mary's Hospital.

L'AFFAIRE SPAHLINGER.

To the Editor of THE LANCET.

SIR,—As one reads, in your issue of March 3rd, the views of three sincerely convinced disciples of M. Spahlinger, one experiences the sensation of being carried away by the enthusiasm of others. A sentence, however, in the obituary notice of the late Prof. Saugman on p. 462 of the same issue brings one back to a more critical frame of mind. Saugman suffered in early adult life from pulmonary tuberculosis and, to quote the notice referred to, "he underwent sanatorium treatment at Dr. Brehmer's Institute in Görbersdorf and, though the disease, even at this stage, was severe and advanced, it was arrested, and he returned to Denmark to take up general practice." His life of unremitting work from 1895 until his death last month, after an operation for gall-stones, shows how surely Nature can limit and inactivate even advanced tuberculous lesions in certain cases. A glance at a paper by Joseph Walsh in the January number of the *American Review of Tuberculosis*, embodying the conclusions formed on "an analysis of 500 necropsies performed or observed" tells the same story. With such facts before us, how can we venture to accept, as evidence for the Spahlinger treatment, the beneficial results that have been noted in the few cases cited by your correspondents? May I suggest, without attempting to make any reflection on the utility of M. Spahlinger's numerous preparations, that the medical profession is still uninformed on certain important points: How are the remedies prepared? How are they standardised? How many cases, and at what clinical stage, have been treated, and for how long have they been observed? How many are now "well and at work," "improved," "stationary," "worse," and "dead"?

It is possible that M. Spahlinger's preparations, or some of them, may yet be proved to be of great value, and if so, he will have conferred a benefit on humanity. But the matter is urgent and time is being lost. What a pity that he does not follow the example of Pasteur, a non-medical scientist, who laid the foundation of modern medicine, by publishing exact details of his methods in order that they may be confirmed by other workers. This would help matters more than the building of an institute for the production of what is, after all, still a "secret remedy."

I am, Sir, yours faithfully,
S. LYLE CUMMINS.
Welsh National School of Medicine, Cardiff,
March 3rd, 1923.

To the Editor of THE LANCET.

SIR,—I should like to say a word in support of what appears in the letter of Dr. Leonard Williams concerning the Spahlinger treatment of tuberculosis. I have seen enough of the results of that treatment, both here and in Geneva, to satisfy me that a prima facie case has been made out; I am most anxious to obtain further supplies of this remedy, and am prepared to support any scheme by which such supplies can be made available for suffering humanity.

I am, Sir, yours faithfully,
BRUCE BRUCE-PORTER.
Grosvenor-street, London, W., March 3rd, 1923.

To the Editor of THE LANCET.

SIR,—As one of the doctors responsible for drawing up the memorandum with regard to this matter, I thank you for your leading article on the subject. May I be allowed to emphasise one fact, which is mainly responsible for the present position? When the war broke out Mr. Spahlinger, who is a Swiss, placed his time and resources at the service of the Allies and set aside his life's aim—the discovery of a cure for consumption—in order to prepare antitetanic serum for the Russian Government. For this work he received not even his out-of-pocket expenses; so that the end of the war found him with greatly diminished resources and his anti-tuberculosis work much in arrear. Now his full supplies of sera and vaccine are very short and the very existence of his laboratory is threatened.

I visited the laboratory last September and was shown over it by Mr. Spahlinger. I saw the complete and original outfit with its automatic checks and safeguards and the beautiful horses and other animals, so well kept and cared for as to be a delight to an English visitor. I also examined many cases, both cured and still under treatment with charts and skiagraphs, and convinced myself that the results, which Mr. Spahlinger has obtained, far exceed anything achieved before in the treatment of advanced tuberculosis. I greatly hope that it will be possible to carry out the course which you advise; for up to now we doctors stand helpless when faced by an advanced case of phthisis, and Mr. Spahlinger, who has never taken one penny for his work or his remedies, is faced by a set-back of five years at least in reaching his goal. This situation is, as you say, "supremely tragic."

I am, Sir, yours faithfully,
PH. NAPIER JONES.

Crowthorne, Berks, March 5th, 1923.

To the Editor of THE LANCET.

SIR,—The enclosure is a note which I prepared for Prof. d'Arsonval's publication in 1921. Since then I have every reason to be still more impressed with the results of Mr. Spahlinger's work, and I am distressed to find that his financial embarrassment is such as may result in a calamity disastrous to the thousands of sufferers who are anxiously awaiting his remedies. I sincerely hope that your valuable influence may help to get Mr. Sphalinger out of his difficult position.

I am, Sir, yours faithfully,
A. H. CROUCHER, M.D., F.R.C.S. Edin.

Eastbourne, March 4th, 1923.

[ENCLOSURE.]

"Being the first doctor to apply Spahlinger's method for the treatment of pulmonary tuberculosis in 1913, I desire to state that all the cases that I know, treated and vaccinated, six years ago, are still alive at the end of 1920, capable of carrying on uninterruptedly their daily occupations in a normal manner. All these patients were in 1913 affected with advanced pulmonary tuberculosis, and two of them had laryngeal complications due to Koch's bacilli. My clinical observations will be published in the report which will be devoted to detailed hospital work. The object of this note is to demonstrate the efficacy of Spahlinger's anti-tubercular vaccination, thanks to which the patient is put in a state to create himself an anti-tubercular immunity strong enough to allow him to cure his lesions, and to combat by his own organism the subsequent attacks of Koch's bacilli.

It is to the admirable effects of this vaccination that we owe the absence of any relapse of the cases cured and vaccinated in 1913 and 1914. A. H. C."

THE ÆTIOLOGY AND OPERATIVE TREATMENT OF HALLUX VALGUS.

To the Editor of THE LANCET.

SIR,—The annotation in your issue of last week on this subject is of considerable interest to orthopædic surgeons, and I should like, with your permission, to state my agreement with the main conclusions reached by Dr. Torsten Sandelin, of Helsingfors. Owing to the absurd but almost universal habit among women of wearing narrow-pointed shoes, hallux valgus is very common indeed; so much so, that, as pointed out in your pages some years ago,[1] it has been considered as the normal condition by some artists and sculptors and even by anatomists. But this deformity, however unsightly, gives rise to few or no symptoms in the majority of cases, even when the deviation of the phalanges outwards amounts to as much as 30 degrees. It seems that it is only when the distorted joint is attacked by arthritis that pain is felt. This is generally of a degenerative and chronic type and results in thinning of the cartilages and hypertrophy of bone, and the most extreme cases of deformity are found in the subjects of rheumatoid arthritis, in some of which abduction to a right angle may be noted. When chronic arthritis has been set up, all treatment other than by operation is only palliative.

My experience entirely bears out Dr. Sandelin's conclusion that excision of the head of the metatarsal bone is the operation to be preferred. After trying lesser or more elaborate methods this is the proceeding which has given me the best results. If the whole of the head and a small portion of the neck of the bone is removed there need be no fear of subsequent stiffness. I have found that the chain saw is a great help to rapidity and neatness, and that it is far superior for the purpose to the wire saw known by the name of Gigli. It is only necessary to keep the toe well flexed during healing, so as to obviate contraction of the extensors. This small operation need not take 15 minutes in its performance, and seems to me to be in its functional results one of the most satisfactory of the minor operations on the skeleton. Incidentally, Dr. Sandelin refers to the transverse arch of the foot formed by the heads of the metatarsal bones. While I am aware that surgeons generally, and perhaps some anatomists, speak of such an arch, I have yet to meet any evidence of its existence in the weight-bearing foot; and in all humility I would ask my confrères to produce such evidence, if they think that they possess it.

The results of the operation in question form a strong argument against the existence of the arch. If it were a reality, the removal of its internal and most massive pier would surely produce some serious disturbance of the stability of the front of the foot, but experience has shown that no such evil result follows excision. On the other hand, the researches of Beely and of Momburg[2] have conclusively proved that the heads of the second and third metatarsal bones are the principal weight bearers of the front part of the foot, and that so far from there being an anterior arch convex above, the curve formed by the line of the metatarsal heads is convex below, when weight is borne by this part of the foot.

I am, Sir, yours faithfully,
E. MUIRHEAD LITTLE.

Seymour-street, Marble Arch, W., March 5th, 1923.

ALCOHOL AND INSANITY.

To the Editor of THE LANCET.

SIR,—Dr. Stanley Wyard's argument, in his letter under this heading in THE LANCET of Feb. 24th, is somewhat difficult to follow. He agrees with the conclusion that alcohol is not an important cause of insanity, but he denies that this conclusion is confirmed by the fact that the enormous reduction of alcoholism during the war was not accompanied by any decrease of insanity. And the reason he gives for refusing any evidential value to this statistical observation is that "other causes of insanity" must be presumed to have been operative during that period to such an increased degree as would have sufficed to counterbalance the effect of the virtual elimination of alcoholism, even if alcoholism had really been the chief factor in the production of mental disease. But surely, if alcoholism is a negligible factor, as Dr. Wyard admits, and if these other alleged causes of insanity, to which he attributes such potency, were active "to a very much greater degree than in pre-war days," there should have been a substantial increase of insanity, and not merely a stationary rate. And what are these other factors of insanity which have been so greatly increased in activity during the war? If Dr. Wyard can identify them and give proof of their causal influence, he is clearly in possession of evidence regarding the ætiology of mental disease which has hitherto been quite unknown to psychiatry.

I am, Sir, yours faithfully,
W. C. SULLIVAN.

Broadmoor State Asylum, Berks, Feb. 25th, 1923.

THE SUSSEX PROVIDENT SCHEME.

To the Editor of THE LANCET.

SIR,—Since you first drew attention to the Sussex Provident Scheme, a little over two years ago, a number of similar contributory schemes have been established all over the country, and it may interest some of your readers who are connected with the other organisations to learn how the Sussex scheme has fared during the past year.

The Group Scheme started on April 1st last year has proved a great success. The number of coöperating hospitals has increased from 9 to 11, but the administration remains in the same hands of a neutral body not connected with any particular hospital, and not seeking representation upon the boards of management of the hospitals. The membership—i.e., 4200 subscribers—and those of their dependents who are beneficiaries under the scheme amounts now to over 10,000, and is rapidly increasing. Although in two cases during the year we have had to pay a hospital over £60 for one member, we have been able to pay every coöperating hospital in full the out-of-pocket cost of their services to our members, based upon the average cost of such services in the year 1921, with the result that since the scheme has been in existence none of our members has depleted the charitable funds of any of the coöperating hospitals of one penny.

---

[1] Boots and Shoes from Historical and Surgical Points of View, THE LANCET, June 20th, 1914, p. 1738.

[2] See Beely, quoted by Momburg in Der Gang des Menschen und die Fussgeschwulst, Berlin, 1920.

With regard to the hospitals not coöperating with us, we are unable to deal direct, and can only repay our members such charges as may have been made to them, but our coöperating hospitals have agreed that when presenting themselves for treatment with their card of membership, and a letter of recommendation from their private doctor, our members shall not be subjected to any almoners inquiry as to their means or asked for any contribution for their maintenance or treatment while attending the hospital, the bill being subsequently sent to the committee of the scheme by the hospital for payment.

We have sustained a great loss in the death of Viscount Selby, who was our honorary secretary, and to whose disinterested service the success of the scheme is mainly due.

I enclose the balance-sheet of the year's working.

I am, Sir, yours faithfully,
P. A. S. CRAWLEY,
Major; Chairman, Sussex Provident Scheme.

THE DISPENSING OF PRESCRIPTIONS.

To the Editor of THE LANCET.

SIR,—I regret exceedingly that Dr. G. Clark Trotter should have felt impelled to write the letter published in his name in your issue of Feb. 24th. The damage done to the reputation of thousands of unoffending pharmacists does not appear to have concerned him in the least. Pharmacists are not responsible for any of the attacks made upon doctors, why therefore, should that be given as a reason for this attack upon pharmacists? I do not defend carelessness on the part of a chemist, but I feel sure that even in Islington, if the true circumstances are known, the proprietors of these pharmacies are not as bad as Dr. Trotter would have everybody think they are, and I am certain that the general standard of accuracy in dispensing is satisfactory throughout pharmacy.

My organisation, through the Pharmaceutical Committee, has been, and is, coöperating with the authorities in securing the highest possible standard for insurance prescriptions. It needs no newspaper stunts to make us appreciate the value of accuracy in dispensing, and we hope that Dr. Trotter will give us credit for trying to be as conscientious as doctors (and he will probably agree that no higher standard need be used). A little more coöperation between medical men and pharmacists would be a great help in securing better fulfilment of the doctors' wishes in regard to their prescriptions. Where that coöperation exists, I have never met with any suggestion that the pharmacist does not do his work properly.

I am, Sir, yours faithfully,
G. A. MALLINSON,
Secretary, the Retail Pharmacists' Union.
19, Tavistock-square, W.C., Feb. 28th, 1923.

RHINO-LARYNGOLOGY.

To the Editor of THE LANCET.

SIR,—In forwarding you a brief note (THE LANCET, Sept. 23rd, 1922) on the treatment of Highmore's antrum I had no intention of precipitating an academic discussion on the subject.

In reply to Sir James Dundas-Grant in your issue of Sept. 30th last, I must first thank him for his pleasant reference to any humble part I may have taken in the work of the specialty in past years. Pace Sir James Dundas-Grant, however, there are some serious objections to procedures detailed in his letter referred to. Mickulicz opening (1886) through the inferior meatus affords imperfect facilities for examining the interior of the antrum and cannot be depended upon for satisfactory drainage. Again, septal spurs defluxions and narrow nares are frequent. Apart from this, two openings are prescribed which upset the acoustic properties of the antrum and might easily lead to a defect in articulation similar to that in cleft palate. If the alveolus is absorbed then there is quite a large pocket left undrained by this meatal opening. Besides, the floor of the antrum generally is below the meatal floor level. Then there is the unfortunate drainage of a suppurating cavity into the nose, postnasum, Eustachian tubes, and possibly to droplet infection into larynx, trachea, and lungs—the fan-like exhaust action in respiration aiding and abetting the evil. Without operation at all, these structures for the most part are irritated in antral disease after an operation by the other route, canine, though irritation promptly disappears.

The simplest procedure in antral disease would seem to be, then, a small trephine opening under cocaine in the canine fossa, free irrigation with the use of bipp (diluted), and watch progress; and if this is retarded then enlarge opening, especially in the presence of ozæna and recurrent polypi. After experience, I have noticed one or two patients who demurred to allowing the opening to close because the daily douching seemed to be so refreshing. Here we have a clue to treatment. In such a large cavity, however, infected massive production of toxin must occur. These patients invariably look septic and rapidly regain health after this simple operation.

I am, Sir, yours faithfully,

Mossel Bay, South Africa. W. ROBERTSON, M.D.

*** Sir James Dundas-Grant writes with reference to the above letter that he is sure his old friend, Dr. Robertson, will find that the objections he raises will quite lose their validity if he gives the operation recommended a trial.—ED. L.

WOMEN IN THE POST OFFICE MEDICAL DEPARTMENT.

To the Editor of THE LANCET.

SIR,—I shall be glad if you will allow me a short space in which to deal with the statements in the memorandum issued by the Federation of Medical Women on the above subject, and published in the issue of your journal of Feb. 24th. It is an axiom that women cheapen labour. The entrance of women into the above department fully bears this out. When a woman M.O. was first appointed in 1882, £150 was taken from the salary of one of the men's appointments and given to her. Neither this sum nor its equivalent has ever been restored to that appointment. Though the bulk of work and responsibility have enormously increased with the growth of the service, the salary is less than it was 42 years ago. Whenever the men in the medical department apply for an improvement in their conditions of service or salary their applications are rejected, one reason being that the women would also expect to partake of any benefit and thus add to the total cost of the concession. The reduction of salary mentioned above involved a reduction of the minimum of that scale, and thus not only affected that particular appointment, but also that of the assistant M.O., as the maximum of his salary could not overlap the minimum of his senior. In one case a man remained 14 years at the maximum of his salary and the Post Office could not grant him any increase.

Worse than the immediate effect on the salary is the ultimate effect on the pension. In the above instances two families were made to live in straitened circumstances in order that a single woman might live in purple. As an indication of the discontent of the women with the conditions of the service it is stated that in 41 years one woman has resigned from the medical staff. Surely no more admirable testimony could be presented to the Postmaster-General as to the attractiveness and comfort of the employment on the women's side of the medical department. It is stated that the men and women are appointed under the same conditions. This is far from being the case. A woman can be appointed as soon as she receives any qualification, at 21 years of age. The woman last appointed was 22. No man is appointed who has not a good qualification, a degree being essential, who has not been a resident M.O. in a large general hospital, and who has not served in the war. In other words, a woman obtains her appointment near 21 years of age without any condition, whilst conditions are imposed upon the men which bring them within range of 30 years of age or over before they are accepted. The claim that the men and women should receive equal pay is ridiculous. At the present time not one of the women has held a resident appointment in a large general hospital, whilst amongst the men there is not one who has not held such a position.

The Postmaster-General naturally pays the women the value of the service they give and not the value of the service given by the men. The Post Office is only a business. Nor will the claim that the women do the same kind of work as the men hold water. There is not a woman on the medical staff at the present moment qualified by knowledge or experience to perform the work of the second M.O. Yet this duty has to be taken up by the men at any moment. Before the demolition of the factory buildings, stores, engineering works at Mount Pleasant, the M.O. to that area had to attend, on an average, 360 accidents of all kinds and degrees, with an abundance of other complicated work, during the course of the year. No woman could possibly perform this duty, nor is there a similar duty under their care. All claims for injuries against the P.O., workmen's compensation cases, visiting provincial offices, examination of special cases of industrial diseases are taken by the men. There is no compulsory qualifying examination for the position of M.O. to the P.O., so that the staff can scarcely be said to "pass the same examination." None of the women, for instance, has obtained a diploma in public health, nor can it be said that a woman with the L.R.C.P. Edin., L.R.F.P.S. Glasg. has passed the same examination as a man with the M.D. Lond, M.D. Camb., &c.

The statement regarding salaries is a farago of nonsense. When the present female M.O. (there is no such appointment as senior female M.O.) was appointed, her scale was £200–£300. The impression is given that this scale was paid to male and female assistant M.O.'s up to 1911. As a matter of fact, the man assistant M.O. who entered the service in 1889 was receiving in 1897 a higher salary than £300 a year. In 1900 he was receiving £400 a year, and in 1906 £450. As previously stated, the P.O. pays salaries according to the value of the work performed, if circumstances permit of this being done. A low initial salary is fixed, for obvious reasons, until the individual has shown ability or otherwise. In the former case the service has its attractions, and rewards.

This matter has been entered into rather fully as misstatements frequently repeated are apt to be accepted as traditional truths.

I am, Sir, yours faithfully,

Feb. 27th, 1923. CLERICUS.

*** Clericus is an advocate, and it is clear that there is another side to many of the situations exposed.—ED. L.

ROYAL LIVERPOOL CHILDREN'S HOSPITAL.—A cheque for over £35,000 was handed to the hon. treasurer of this hospital on Feb. 23rd as a result of a bazaar held last December. The hospital had previously been in debt to the extent of £22,000. At the recent annual meeting Dr. Alfred Holt, the President, referred to the savings effected by the amalgamation with the country branch at Heswall. By these means and the success of the bazaar, he hoped to be able to prevent the recurrence of such financial stringency as in the past.

The Services.

NORTH PERSIAN FORCES MEMORIAL MEDAL.

The War Office announce the institution of a Memorial Trust Fund, commemorative of the services of the late North Persian Forces, which has been subscribed by officers of the Royal Army Medical Corps and Indian Medical Service who served with these forces. In accordance with the desire of the subscribers to encourage the study of tropical medicine and tropical hygiene, it has been decided that the memorial should take the form of a silver medal, to be known as the "North Persian Forces Memorial Medal," to be awarded annually for the best paper on tropical medicine or tropical hygiene published in any journal during the 12 months ending Dec. 31st by any medical officer, of under 12 years' service, of the Royal Navy, Royal Army Medical Corps, Royal Air Force, Indian Medical Service, or of the Colonial Medical Service. The first award will be for the best paper published during the 12 months preceding Dec. 31st, 1923. The award will be announced in the latter part of the year following that in which the paper was published, provided that the Memorial Committee consider the papers published to have attained a standard of merit justifying an award.

ROYAL NAVAL MEDICAL SERVICE.

Surg.-Cmdr. T. B. Shaw succeeds Surg. Capt. R. Bond as Professor of Hygiene and Director of Medical Studies at the Naval Medical School, Greenwich.

ROYAL ARMY MEDICAL CORPS.

Majs. to be Lt.-Cols.: E. E. Parkes to complete estabt.; R. V. Cowey, vice Lt.-Col. A. W. N. Bowen, ret. pay; J. S. Bostock (Bt. Col.) and to remain secd., vice Lt.-Col. D. Harvey, promoted; W. J. Waters, vice Lt.-Col. and Bt. Col. J. S. Bostock secd.; H. F. Shea and to remain secd., vice Lt.-Col. F. P. Lauder, ret. pay; and T. B. Unwin, vice Lt.-Col. H. F. Shea, secd.

Maj. J. H. Barbour retires on ret. pay.

Capts. to be Majs.: B. Biggar (and to remain secd.), C. M. Finny, J. D. Kidd (Bt. Maj.), G. Wilson, E. G. S. Cane, F. A. Robinson, W, A. Frost (Temp. Maj.), D. Reynolds, C. D. K. Seaver, W. T. Graham, W. Bisset, W. L. E. Fretz, P. Hayes, P. M. J. Brett, and T. C. R. Archer.

Temp. Capts. B. F. Haythornthwaite and W. C. McKee relinquish their commns. and retain the rank of Capt.

MILITIA.

Capt. R. B. Campion relinquishes his commn. and retains the rank of Capt.

Capt. C. H. Vernon resigns his commn. and retains the rank of Capt.

Capt. W. K. Churchouse (late R.A.M.C., T.F.) to be Capt.

Lt. J. W. Hirst (late Duke of Wellington's Regt.) to be Lt.

General Hospitals: The undermentioned relinquish their commns. and retain their rank except where otherwise stated: Capts. G. H. Colt (granted the rank of Maj.), N. S. Finzi, H. Peterkin, J. J. Rainforth (granted the rank of Maj.), C. W. Sharpley, G. W. Goodhart, F. V. Milburn, and R. Richards.

Capt. J. B. F. Wilson relinquishes his commission and is granted the rank of Maj.

Sanitary Companies: Capts. J. Chalmers and C. H. Lilley relinquish their commns. and retain the rank of Capt.

TERRITORIAL ARMY RESERVE.

Capt. H. N. Barnett, from Gen. List, to be Lt.-Col.

Capt. L. J. E. McHugh, from Gen. List, to be Maj.

Capt. T. H. W. Alexander, from 1st Scottish Gen. Hospital, to be Capt.

Capt. F. G. Caley, San. Co., relinquishes his commn. and retains the rank of Capt.

ROYAL AIR FORCE.

Flight Lt. (actg. Squadron Leader) F. C. Kempson relinquishes his temporary commission on ceasing to be employed, and is permitted to retain the rank of Maj.

INDIAN MEDICAL SERVICE.

H. Watts-Taylor, J. Carrey, L. G. Pearson, L. B. Jones, and W. C. McKee to be Capts.

H. McNair, C. R. Henderson, I. C. Robertson, and M. Taylor to be Lts.

The King has approved the retirement of Lt.-Cols. W. H. Dickinson and W. J. Niblock.

Medical News.

Society of Apothecaries of London.—At examinations held recently the following candidates passed in the subjects indicated:—

Surgery.—M. Hawke, Guy's Hosp.; L. D. A. Hussey, King's Coll. Hosp.; C. M. John, Royal Free Hosp.; and S. W. Turtle (Sect. II.) and A. Vasudev, London Hosp.

Medicine.—K. C. Chock, Creighton University, U.S.A.; S. E. Hymans de Tiel, Royal Free Hosp.; C. S. Laurence, Bristol and Sydney; J. A. Marriott (Sect. II.), Manchester; O. F. W. Robinson, King's Coll. Hosp.; and S. W. Turtle (Sect. II.) and A. Vasudev, London Hosp.

Forensic Medicine.—K. C. Chock, Creighton University, U.S.A.; S. E. Hymans de Tiel, Royal Free Hosp.; J. A. Marriott, Manchester; O. F. W. Robinson, King's Coll. Hosp.; and A. Vasudev, London Hosp.

Midwifery.—F. Bienaschewitsch, Berne and Petrograd: E. W. Hicks, St. Thomas's Hosp.; and J. A. H. Sykes, Edinburgh.

The Diploma of the Society was granted to the following candidates, entitling them to practise medicine, surgery, and midwifery: J. A. Marriott and S. W. Turtle.

Royal Society of Arts.—On March 16th, at 4.30 p.m., Sir Leonard Rogers will read a paper before the Dominions and Colonies and Indian sections on Recent Advances Towards the Solution of the Leprosy Problem. The chair will be taken by Earl Winterton, and a discussion will follow the paper. On March 21st, at 8 p.m., an ordinary meeting of the Society will be held, when Dr. F. W. Edridge-Green will lecture on Some Curious Phenomena of Vision and their Practical Importance, Prof. E. H. Starling presiding.

Federation of Medical and Allied Services.—A meeting of the Executive Council was held at the offices, 12, Stratford-place, London, W., on Feb. 27th. The following lay organisations were elected corporate members: the British Red Cross Society, Messrs. Vickers, Ltd., Messrs. Debenhams, Ltd., the Legal and General Assurance Society, the South Metropolitan Gas Co., the National Insurance Beneficent Society, and the Joint Committee of Approved Societies.

The Council considered its present attitude to the National Health Insurance Medical Service and what steps, if any, should be taken to secure the setting up of the Royal Commission promised, in response to its representations, by the late Minister of Health to inquire into the working of the Acts.

International Congress of Mental Hygiene. The Ligue Française d'Hygiène Mentale, the Ligue Belge d'Hygiène Mentale, and the United States National Committee of Mental Hygiene will participate in a congress at New York in April, 1924. Among the subjects to be considered are the abuse of stupefying drugs, the reorganisation of teaching of backward children, and child welfare generally, reform of penal systems, psycho-physiological vocational selection, and the technique of psycho-therapy. Any European society desirous of participation in the congress is invited to communicate with Dr. Genil-Perron, general secretary, Ligue d'Hygiène Mentale, 99, Avenue de la Bourdonnais, Paris.

Congress of Obstetrics and Gynæcology.—The fourth annual British Congress of Obstetrics and Gynæcology will be held in Edinburgh on April 19th and 20th, with a possible extension to the 21st. The gathering is a conjoint meeting of the various obstetrical and gynæcological societies in the United Kingdom and Ireland—viz., the Royal Society of Medicine (Section of Obstetrics and Gynæcology), the Edinburgh Obstetrical Society, the Glasgow Obstetrical and Gynæcological Society, the Midland Obstetrical and Gynæcological Society, the Royal Academy of Medicine in Ireland (Obstetrical Section), the Ulster Medical Society, and the North of England Obstetrical and Gynæcological Society. On this occasion the Edinburgh Obstetrical Society hopes to welcome a large number of representatives from the other societies. The Royal College of Surgeons of Edinburgh has granted the use of its hall for the discussions, and the Royal College of Physicians of Edinburgh is allowing the use of its hall for a dinner which will be held on the evening of the 19th. The main discussion on the first day of the congress will be upon intrinsic dysmenorrhœa, regarding the main features of which a report embracing information and statistics from different parts of the country will be presented. There will be opportunity also for a number of short papers on other subjects, and for the exhibition of specimens of special interest. Notice of such papers or specimens should be sent as soon as possible to the secretaries of the Edinburgh Society, Dr. H. S. Davidson, 52, Melville-street, Edinburgh, and Dr. James Young, 29, Manor-place, Edinburgh. Those who intend to be present are also requested to notify the secretaries either directly or through their own society.

Colonel Sir William R. Smith, Senator Dr. D. B. Hewat, and Dr. Herbert G. Tymms have been appointed Knights of Grace of the Order of St. John of Jerusalem in England.

THE Royal Northern Hospital, Holloway, London, N., has received an anonymous donation of £500 in response to its appeal for the nurses' home. £10,500 are still required in order to meet the estimated cost of building the first section on a site already secured.

MEDICAL WOMEN'S FEDERATION.—A dinner will be held by the Federation in the Empire Rooms, the Trocadero, Shaftesbury-avenue, W., on May 10th, at 7.30 for 8 P.M. Communications should be addressed to the secretary, 9, Clifford-street, Bond-street, London, W.

NATIONAL COLLEGE OF TEACHERS OF THE DEAF.—The annual meeting of the College will be held on March 17th at the Bonnington Hotel, Southampton-row, W.C. Lord Charnwood, the President, will deliver an address.

MEDICO-LEGAL SOCIETY.—A meeting of this society will be held at 11, Chandos-street, W., on March 20th, at 8.30 P.M., Lord Justice Atkin, the President, in the chair. Dr. H. A. Burridge will read a paper on State Effort to Rescue Drug Victims, with special reference to the Dangerous Drugs Act.

INSTRUCTION IN HOSPITAL ADMINISTRATION.—A three months' course of lectures and demonstrations in hospital administration will be given at the North-Western Hospital, Lawn-road, Hampstead, London, N.W. 3, by Dr. E. W. Goodall, medical superintendent, on Mondays and Thursdays, at 5.15 P.M., beginning on April 5th. Medical men desiring to attend the course of instruction are requested to send their full name and addresses to the Clerk to the Metropolitan Asylums Board, Victoria Embankment, London, E.C. 4.

TUBERCULOSIS SOCIETY.—A meeting will be held in the Council Chamber, Council House, Bristol, on March 16th, at 10 A.M. At the morning session Prof. Lyle Cummins and Dr. E. Ward will speak on Tuberculosis and Pregnancy, and Dr. Henry Ellis and Dr. Campbell McClure on Reactions relating to Tuberculosis. In the afternoon Dr. H. de Carle Woodcock will give an address on the Physique of the Phthisical, Dr. Halliday G. Sutherland, Dr. T. Nelson, and Dr. Richard Clarke will discuss Difficulties in Diagnosis, and Dr. W. C. Rivers will give a paper on the Domiciliary Treatment of Osteo-Articular Tuberculosis. On March 17th, at 10 A.M., Dr. T. Nelson will give a demonstration of the results of treatment by artificial pneumothorax. Visits will be paid to Frenchay Park Sanatorium and Ham Green Sanatorium.

FOREIGN DECORATIONS.—The following decorations for services rendered during the war have been granted: Médaille de la Reconnaissance Française en Argent to Lieut.-Colonel J. Miller, R.A.M.C. (T.), by the President of the French Republic; Commander of the Order of St. Maurice and St. Lazarus to Major-General Sir Foster R. Newland, A.M.S. (retired pay); and Chevalier of the same Order to Captain T. D. Inch, R.A.M.C. (Reserve of Officers), by the King of Italy.

LINCOLN COUNTY HOSPITAL.—A contributory scheme for the hospital was adopted by the Governors at a meeting held on Feb. 20th. Captain H. T. W. Nevile, R.N., chairman of the Board of Management, outlining the scheme, said if an adequate income were to be raised to maintain the institution, it was absolutely necessary that some action should be resolved upon. Since 1919 the deficit caused by excess of expenditure over receipts had been accumulating, and it now stood at £4343 4*s.* 4*d.* The board, after studying what had been done in other places, concluded that the best way of raising and maintaining an adequate income was by means of a contributory scheme. They had found that the income required when the new ward was completed would be about £19,000 a year. The scheme laid down that contributions asked for from the city and the country area must be in proportion to the work done for each; that patients from places which did not come into the scheme must pay the actual cost of their treatment; and that patients from places which did not contribute the full amount asked for under the scheme would have to pay a proportional part of the cost of their maintenance. Local hospital associations are to have representation on the board of governors and the recommending of patients. Mr. R. B. Purves, surgeon to the hospital, said that unless some such action as that proposed was taken they would meet with a steady decline that would ultimately mean State control. He believed that any hospital not able to stand on its own legs, and moreover unable to go ahead and keep improving, would be swept into the net in time.

ROYAL LANCASTER INFIRMARY.—This hospital is in the fortunate position of being out of debt, has a small credit balance on the year's working, and a sum in hand for extensions and development. The income for the year was £10,952 and the expenditure £8555, which enabled the committee to wipe out an adverse balance of £2016. There was a large increase of subscriptions from workpeople under the new contributory scheme—from £1350 in 1921 to £3351 in 1922. A bazaar last year added £5743, whereby the debt on the extension fund was wiped off and a sum set aside for developments and improvements. Altogether from legacies, special gifts, and the bazaar £11,679 were received by the infirmary committee during the year.

COÖPERATION BETWEEN MEDICAL OFFICERS OF HEALTH AND PRACTITIONERS IN MANCHESTER.—A gathering of the medical profession in Manchester met on Feb. 28th in the Town Hall, at the invitation of the Lord Mayor, to meet the new medical officer of health, Dr. Veitch Clark. Dr. Clark, in a short speech, said there was nothing more fundamental to the success of modern preventive medicine than a whole-hearted friendship between that part of the medical profession officially representing the city and those who were practising among the citizens. The greatest of all natural laws was the law of continuity. Up to the end of last century public health administration was mainly concerned with things which, though they were essential for the welfare of the community, were not specifically medical—the provision of good water-supplies, means of dealing with sewage, and so on. In this century, however, the profession had entered upon a new line of work—a direct attack upon disease. The primary function of his department was one of prevention. By working wholeheartedly together the medical profession was following on the lines which would in the end produce the greatest benefit to the public.

LEICESTER PUBLIC MEDICAL SERVICE.—At the annual meeting held on Feb. 13th the report for 1922 of the Leicester Public Medical Service was presented, together with the annual report for that year of the committee of the Leicester Subdivision of the Union of Medical Practitioners. The number of subscribers to the various sections of the Public Medical Service was 39,706 in the first half, and 39,441 in the second half of the year, against 39,097 and 38,935 respectively in 1921. The rate per capita paid to "acting members" of the Service for attendance on uninsured subscribers was the highest rate yet paid. The Board of Management has continued the arrangement whereby free treatment is provided for the uninsured blind of Leicester under the care of the Institution for the Welfare of the Blind, the Wycliffe Society for helping the Blind, and the members of the Cripples' Guild. The number of prescriptions issued during the year was 195,097, against 185,260 in 1921. The arrangement with the education committee for accommodation to be provided at the central dispensary for the dental work of the school clinic has been continued: 3607 new cases, in addition to many others, were treated during the year. By arrangement with the Ministry of Health a consulting room at the central dispensary was again provided for the purposes of the regional medical officer, and greatly increased use was made of it. Drugs, &c., were supplied during the year to several members of the Service, the account amounting to a little over £94. The hope is expressed that more members of the Service will avail themselves of this materially advantageous system. The Board again arranged with the Leicester guardians for dispensing medicines for the outdoor sick poor. The total amount received by the Public Medical Service during 1922 amounted to £21,122 14*s.* 4*d.* on the general account, and to £326 19*s.* 7*d.* on the furniture and renovation account. In the report of the committee of the Leicester Subdivision of the Union of Medical Practitioners it was stated that the scheme for collective locum-tenencies during sickness short absences was in operation from Oct. 1st, 1921, to March 31st, 1922. Three doctors availed themselves of the scheme; a sum of £34 11*s.* 11*d.* was available for distribution, which was made at the rate of 1*s.* 7*d.* per unit, the units numbering 437. The scheme of collective locum-tenencies was successfully continued from April 1st to Sept. 30th, 1922; 17 doctors took advantage of the scheme; a sum of £195 10*s.* 4*d.* was available for distribution, which was made at a rate of 1*s.* $8\frac{9}{16}$*d.* on a total number of 2282. The committee expressed in the report their appreciation of the measure of support their proposals met with. By the majority of panel practitioners consenting to a levy in the aggregate of 1*d.* per annum for each insured person on their lists, the committee were enabled from the amount thus received to defray the expenses of the Leicester Sub-Division of the Union of Medical Practitioners, and the expenses of the panel committee, to contribute about £100 to medical and allied charities, £185 to the National Insurance Defence Trust, and £35 to the Medical Representation in Parliament Fund.

Royal (Dick) Veterinary College, Edinburgh. It is proposed to found a post-graduate research Fellowship as a permanent memorial of the centenary of the foundation of this College in November, 1823. Funds for this purpose should be sent to Dr. O. Charnock Bradley, the Principal, from whom further information may be obtained.

Medical and Dental Registers. — We have received a copy of the Medical and Dental Registers for 1923. The Medical Register has 1240 pages devoted to practitioners registered as qualifying from medical schools in the United Kingdom and Ireland, 76 pages to colonial medical men, and 3 pages to foreign graduates registered in this country. The corresponding figures for 1922 were 1214, 66, and barely 3. The total number of persons now on the register is 46,477, against 45,408 in 1922. The Dental Register consists of 310 pages, against 146 in 1922, showing the increase due to registration of practising dentists under the new Act.

Precautions against Small-pox.—Several new cases have been notified at Clowne, Derbyshire, where there has been a mild epidemic for some considerable time. At Bentley also, near Doncaster, where about 20 cases have already been notified, another case has been reported, while at Doncaster itself 11 new cases have been notified within the past few days. The Lancashire Asylums Board, as a precautionary measure, have issued a notice that no visitors can be allowed to see their friends at the County Mental Hospital, Whittingham, Preston, for the present, and no parcels can be received.

Crichton Royal Institution, Dumfries.—The report of this Institution for 1922 records a number of structural changes postponed during the stringent years of the war. As in the case of many similar institutions, the influence of war conditions persists in the form of structural depreciation, and in spite of the general fall in prices; the moderate increase in fees which was made has, therefore, to be maintained for the present. The reputation of the Institution is well supported by the fact that nearly 30 per cent. of the private patients during last year were voluntary boarders. No particulars are given of the forms of mental disorder from which these patients suffered, which is the more unfortunate since the degree and varieties of mental illness compatible with voluntary status are the subject of some difference of opinion. To the officers of institutions where certification is recommended more freely such information would be of value and interest. Its necessity is the greater for the fact that the death-rate among these voluntary boarders was considerably higher than in the case of the certified patients. These data are open to the inference that senile cases and general paralysis are admitted on a voluntary basis, a practice unusual in this country. The laboratory work, for which the Crichton Royal Institution is known, is at present curtailed owing to a vacancy in the post of pathologist, and no record of this work during the past year is given.

Donations and Bequests.—The late Sir Carl Meyer, of Newport, Essex, and of Park-crescent, has left by will £1000 each to King Edward's Hospital Fund for London and the National Hospital for the Paralysed and Epileptic, and £500 to the Saffron Walden General Hospital.—By the will of the late Mr. John William Horsfall, of Halifax, the testator left £10,000, free of duty, to his trustees for any charitable purpose or purposes at their discretion; £500 to the Royal Halifax Infirmary; £250 each to the Halifax Branch of the National Society for the Prevention of Cruelty to Children and Dr. Barnardo's Homes; and £100 each to the Halifax Police Court Mission and the Society for the Home Teaching of the Halifax Blind.—Dr. Ellis Thomas Davies, of Liverpool, left £10,560, and directed that the ultimate residue of the property as to one-fourth be given to the Royal Benevolent Fund, one-fourth to the Medical Faculty of the University of Liverpool, one-fourth to University College, Bangor, for a scholarship for aiding poor and deserving Welsh students of either sex, and the remaining fourth to certain Wesleyan Missions. His engraving of the late Lord Lister the testator left to the Liverpool Medical Institute.—The Board of the Bradford Dyers Association, Ltd., have decided to make a donation of £5000 to the Bradford Voluntary Hospitals in response to the special appeal by the Lord Mayor. Other donations authorised were £250 to the Bradford Royal Infirmary, £50 each to the Manchester Royal Infirmary, the Salford Royal Hospital, the Royal Albert Asylum, Lancaster, £40 to the Royal Halifax Infirmary, £20 to the General Infirmary, Leeds, and £10 to a number of hospitals and associations.—A gift of £1000, in the interests of Medical Missions of the Wesleyan churches, in memory of the late Miss Emily M. P. Wood, of Southport, is announced.—The local hospitals of Manchester and Salford will benefit to the extent of over £2000 as the result of the Manchester Students' "Rag" on Shrove Tuesday. Last year's effort realised £1265.

Parliamentary Intelligence.

HOUSE OF COMMONS.

Wednesday, Feb. 28th.

Dangerous Drugs and Poisons Bill.

On the motion for the second reading of the Dangerous Drugs and Poisons (Amendment) Bill,

Mr. Bridgeman (Home Secretary) said the object of the measure was to increase the facilities and powers for dealing with the illicit traffic in drugs which was very largely of an international character. Under Clause 1 they were seeking for increased powers of search so as to discover the persons who were carrying on this trade in secret places. The second power for which they were asking—in Clause 2—was intended to bring within the penal provisions of the Bill acts done in this country with a view to illicit transactions abroad. They were also of opinion that the existing penalties were inadequate in cases where persons were engaged in these drug transactions in a large way. Enormous profits were made. In an instance which he heard of recently it was believed that someone got as much as 2400 oz. of morphine and 2500 oz. of cocaine which represented several million doses. France had already increased the penalties in such cases and the Council of the League of Nations recommended to the Governments concerned to consider the question of more substantial sentences of imprisonment. It was therefore proposed to substitute for the existing penalties a maximum of ten years' penal servitude or a fine of £1000, or both, in cases of conviction on indictment, and secondly, a maximum penalty of 12 months' imprisonment or a fine of £250, or both, in cases tried summarily. It was proposed to do away with the provisions for increasing the penalty for a second offence. Provisions in Clause 3 were meant to meet a difficulty which the Pharmaceutical Society brought to the notice of the Government in regard to supplying drugs to duly qualified medical practitioners. Under the Pharmacy Act, 1868, there was a "poison book" which everyone was expected to sign if they bought any of these drugs at a chemist's shop, but it was impossible in practice, he believed, to observe that provision, and it had been allowed largely to fall into disuse. Under Clause 3 they wished to prevent, if they could, people professing to come for medical practitioners to order these drugs at chemist's shops, to make it quite clear that they were required for a medical practitioner and to safeguard, if they could, the transit between the shop and the practitioner. The seller had to enter in a book the words "signed order" instead of requiring the doctor to sign, and if the article was sent by post it must be sent by registered post, and must not be sold to anybody except a registered medical practitioner in actual practice. It was possible that some of the medical profession might wish to have some slight modification of this clause which he would be very ready to consider, but it was very important to rectify the position in which they were left by the fact that Section 17 of the Pharmacy Act was not suitable to present conditions.

Sir F. Banbury thought that the Bill was a very drastic one and not very clear in regard to some of its provisions. He would not oppose the second reading, but he thought the measure required very careful amendment in committee.

Sir Sydney Russell-Wells said he supposed that medical men were more acquainted with the dangers, the temptations, and the horrors to which the drug-taker was exposed than any other portion of the community. Neither he nor any other member of his profession would wish to interfere with the intention of the Government to stop the illegal sale and improper use of these dangerous drugs as far as possible. But while not wishing to oppose the second reading of the Bill he thought that it would require drastic amendment. In regard to the suggested increased penalties they must remember that this Bill and the Act to which it was an amending measure created various offences other than the intentional and nefarious traffic in dangerous drugs. It would have been better if the precedent of the Food and Drugs Act had been followed and the various offences had been scheduled and classified with appropriate maximum penalties attached to each. This would sooner or later have to be done or the Acts would become a dead letter. A doctor who, from carelessness or hurry, omitted to make the proper entries in the books he was compelled to keep, or who did not retain the invoices of the drugs he had bought, would be liable to a fine of £1000 or to be imprisoned for ten years, or both, just as if he had been guilty of providing a drug-taker with 10 lb. of cocaine. That was ridiculous. There was more reason for alarm with regard to the penalties to be inflicted on summary conviction. Again, any medical man who prescribed one of these remedies for himself was guilty of an offence against the Act. No doubt certain doctors were drug-takers, but he was convinced that their number was very small. He regretted that there was no provision in this amending Bill for sweeping away this ridiculous regulation. First of all, it hampered the doctor unnecessarily by creating a new offence, and secondly, as a preventive it was futile. Drugs must be in the doctor's consulting-room for cases of emergency, and he supposed there was not one practitioner in a thousand who did not constantly carry with him a case in which there was a certain quantity of morphia or cocaine or both for emergency use. The prohibition to prescribe for himself in no way affected the medical man's power of obtaining a drug if he wished to take it. But should he write a prescription for himself he committed an offence which rendered him liable to all the dire penalties prescribed by the Bill. When it came to a question of prescribing drugs to relieve pain doctors, he believed, would be willing to break the law in order to give relief. And in this he was certain public opinion would support the profession. Clause 3 of the Bill contained quite a new provision. It applied to all poisons and not simply to cocaine and morphia, and these regulations would stop any medical man getting any poisonous drug without definitely signing and sending a document. In a case of confinement with severe hæmorrhage, for example, a doctor would require certain drugs which he would not usually carry with him. He could not leave the patient and there might be no one to send. If he telephoned the chemist would, under this Bill, not be allowed to send the drug. He wondered if hon. Members were aware of the amount of drugging carried on by means of patent medicines. He had known cases where morphia fiends got their morphia through purchasing chlorodyne. The Government should insist that every patent medicine should have on its label the substances it contained, or at any rate, the poisonous substances and the exact proportion in which they existed. He thought he might speak on behalf of the medical Members of the House, because he was secretary of the committee of medical Members, and they urged most strongly that the Government should seriously revise the Bill and should take into conference those who were engaged in the actual practice of medicine.

Major MOLLOY said that the Bill had his complete sympathy so far as its principles were concerned. He represented, however, a very much harassed and hard-working class of people, the general practitioners of medicine and surgery, upon whom certain provisions of this Bill would bear very hardly. He urged that amendments were necessary in respect of the penalties to which medical men might be liable for a purely technical offence; the facilities for obtaining drugs in an emergency; and the prohibition imposed upon a practitioner to prescribe drugs for himself.

Mr. BRIDGEMAN, replying to the debate, said he was quite ready to listen to any suggestions for making certain provisions of Clause 3 more workable, and he hoped that the medical Members of the House and those they represented would supply him with some form of words which would effect his purpose without doing them any injury.

Dr. CHAPPLE said this piecemeal legislation was very largely wasting the time of the House. The evil that was being done to the community to-day was not to be measured by the scope of this Bill. Patent medicines containing many of these very drugs were being advertised all over the kingdom and were creating a craving in hundreds of thousands of people.

The motion for the second reading of the Bill was agreed to.

Cost of Medical Insurance Benefit.

Mr. RHYS DAVIES asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, the amount annually expended in England and Wales out of national health insurance funds in the provision of medical benefit by insurance practitioners in the provision of drugs and appliances to insured persons, respectively; and, as far as his knowledge extended, the amount similarly expended in Scotland and Ireland.—Sir W. JOYNSON-HICKS replied: The amounts annually expended in England and Wales out of national health insurance funds are approximately: (1) Provision of medical benefit (excluding drugs) by insurance practitioners, £6,520,000; (2) provision of drugs and appliances, £1,280,000. The amounts similarly expended in Scotland are (1) £870,000 and (2) £160,000. Medical benefit is not provided to insured persons in Ireland.

Institutional Treatment for Tuberculosis.

Mr. TOM WILLIAMS asked the Minister of Pensions (1) how many ex-Service men entitled to pensions were at present receiving institutional treatment for pulmonary tuberculosis in sanatoriums; and (2) the cost per week per patient to the pensions department.—Major TRYON replied: Approximately 3000 ex-Service men are at present receiving residential treatment in institutions for tuberculosis. The average cost of treatment is £2 17*s.* 6*d.* a week for each patient, and, in addition, treatment allowances averaging £2 a week for each patient are paid by my department.

Food Adulteration Prosecutions.

Mr. TOM WILLIAMS asked the Secretary for the Home Department the number of prosecutions and convictions for adulteration of food during the years 1921 and 1922.—Mr. BRIDGEMAN replied: According to the annual returns of crime for adulteration of food, drugs, &c., there were 3555 persons proceeded against in 1921, of whom 2329 were convicted, while in 1922, 2400 persons were proceeded against for offences of this kind, of whom 1586 were convicted. The figures for 1922 are provisional only. The figures for 1921 include offences against the Beer and Spirits (Prices and Descriptions) Orders now repealed.

State Examination for Nurses.

Dr. CHAPPLE asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether any curriculum had been drawn up prescribing the course of training for nurses qualifying under the Nurses Registration Act, 1919; and whether any provision had been made for holding a State examination for nurses.—Viscount WOLMER replied: The General Nursing Council have submitted a draft syllabus of training and examinations and my right hon. friend is now in communication with the Council in regard to them. Arrangements for conducting examinations which will be held by the Council and not by the Ministry have not yet been made.

Cost of Pauper Lunatics.

Mr. ALBERT ALEXANDER asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether boards of guardians had informed him that the present charge per head for pauper lunatics was excessive, and that in view of the heavy charges made upon the Poor-law authorities for the maintenance of the pauper lunatics boards of guardians should have representation upon the various asylums boards; and what steps he proposed to take in the matter.—Viscount WOLMER replied: The answer to the first part of the question is in the affirmative. It is not possible to deal with this matter without legislation which it would not be practicable to introduce at present, but the point has been noted for consideration when any general amendment of the Lunacy Acts is undertaken.

Milk (Special Designations) Order.

Mr. HOPE SIMPSON asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether his attention had been called to the fact that the provisions of the Milk (Special Designations) Amendment Order, 1922, now lying upon the table of the House, required the employment of a plant for pasteurisation, the expense of which was beyond the means of the smaller retail dairyman; whether he had received any representations on the point; and whether the danger that the application of this Order would tend to increase the power of the milk combine had been brought to his notice.—Viscount WOLMER replied: Some representations have been made to my right hon. friend in the sense suggested by the hon. Member, but he does not regard them as sufficient to justify a departure from the principles on which the Order has been made. "Pasteurisation" is a designation applied to milk which has been subjected to certain heating processes, as set out in the Order. It is obvious that such processes cannot be undertaken except by the adoption of the necessary means or machinery, entailing some capital expenditure. My right hon. friend wishes to point out that there is nothing in the Order to compel any dairyman to pasteurise the milk he offers for sale.

Accommodation in Tuberculosis Sanatoriums.

Mr. RHYS DAVIES asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, the number of persons at any recent given date notified as suffering from tuberculosis who had failed to secure admission to sanatoriums.—Viscount WOLMER replied: The number of persons recommended for and awaiting treatment for tuberculosis in residential institutions from local authorities in England and Wales on Feb. 1st, 1923, was 2902, on which date 16,393 persons were receiving such treatment and there were a number of vacant beds. My right hon. friend is not aware of the number of notified cases which have not been admitted to residential institutions, but the hon. Member no doubt appreciates that not all notified cases of tuberculosis require, or are willing to receive, such treatment.

Unemployment Insurance and Hospital Staffs.

Colonel Sir CHARLES BURN asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether it was intended to return the whole or any part of the contributions on account of unemployment insurance paid by nurses, including sisters, and hospitals during the period of two years, in view of the fact that no benefit would accrue to the parties who made them from such payments; and, if not, why not; and what was the amount of contributions paid by or in respect of hospital nurses and sisters from July 1st, 1920, to June 30th, 1922.—Sir M. Barlow (Minister of Labour) replied: I have no power to refund these contributions. It would be a laborious undertaking to ascertain the amount of contributions paid by nurses or of the benefit drawn by them. I would point out, however, that when the proposal for the exclusion of nurses was before Parliament it was ascertained that a considerable number of nurses were drawing benefit and in view of this a definite understanding was arrived at that contributions should be paid by nurses up to July, 1922.

Cost and Scarcity of Insulin.

Dr. Chapple asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether, in view of the fact that the cost and scarcity of insulin were depriving many poor sufferers from diabetes of the measure of cure which it was able to provide, he would make a special grant in aid of its more rapid and abundant production.—Viscount Wolmer replied: It is not the case that the poor only are deprived of the advantages of insulin, which cannot be made available until a supply of known efficiency, potency, and safety is attained upon a manufacturing scale. Considerable progress has been made by the Medical Research Council in this direction, and the Council believe that subject to limitation of raw material in particular districts, the successful manufacture of insulin in the near future is assured. No special grant in aid would accelerate production at this stage.

Compulsory Pasteurisation of Milk.

Mr. Becker asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether it was the Government's intention to introduce a Bill to compel pasteurisation of all milk for human consumption.—Viscount Wolmer replied: The answer is in the negative.

Sanatoriums in Great Britain.

Mr. Tom Williams asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, the total number of sanatoriums in Great Britain, with the approximate or actual accommodation; the number of cases who were waiting for sanatorium treatment; and what steps he intended to take to meet the situation.—Viscount Wolmer replied: The number of residential institutions approved by my right hon. friend for the treatment of tuberculosis in England and Wales is 455, with a total accommodation of about 20,555 beds. On Feb. 1st 2902 cases were awaiting residential treatment, but as there was a number of vacant beds on that date it is probable that many of these cases have now been admitted to institutions, and my right hon. friend does not consider it necessary to take any special steps in the matter.

Adolescents and Drunkenness.

Mr. Greaves Lord asked the Home Secretary what number of persons under the age of 18 had been charged with drunkenness during the years 1919, 1920, 1921, and 1922, and how many such persons had been convicted.—Mr. Bridgeman replied: The only figures I can give are those of convictions in the age groups used in the criminal statistics, thus: 1919, no convictions under 16 years of age, 2610 between 16 and 21; 1920, 2 under 16, and 4063 between 16 and 21; 1921, 2 under 16, and 2172 between 16 and 21. The figures for 1922 are not yet available.

Charges against Panel Practitioners.

Mr. Burgess asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, if he was aware that private patients very often receive priority of attention when medical practitioners had a combined practice; that many patients requesting home attendance were asked to call at the surgery; that many panels were too large to secure efficient service to insured persons; and what steps he proposed to take to improve these conditions.—Viscount Wolmer replied: The information available to the department does not indicate that the practices to which the hon. Member refers are generally prevalent, but if he is aware of specific cases in which insurance practitioners have failed to carry out their obligations, my right hon. friend hopes that he will report them to the local Insurance Committee concerned with a view to investigation and disciplinary action if the complaints are established. If an insurance committee find that inefficiency of service is due to the acceptance by the practitioner of too great a number of insured persons they have power, after consultation with the Panel Committee, to reduce his list.

Assistance for Dental Students.

Mr. Albert Alexander asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, whether he was aware that the Dental Board of the United Kingdom had informed the candidates concerned that the scheme for educational assistance and maintenance to those who desired to qualify under the Dentists Act, 1921, would not be considered until the end of May; that this delay was causing great hardship to a large number of ex-Service and other candidates who had been arbitrarily excluded from the profession under Section 3 (1) (3) of the Dentists Act, 1921; and whether, in view of the fact that the Dentists Act had now been upon the Statute Book for more than 18 months, he would take immediate steps to expedite the completion of the scheme or, alternatively, to make some other provision for those who were now without either employment or maintenance.—Viscount Wolmer replied: The reply to the first part of the question is in the affirmative. As regards the second part the age-limit is statutory, and no objection was raised on this point when the Bill was under discussion in the House. As regards the third part of the question my right hon. friend has no jurisdiction over the Dental Board in this matter.

Friday, March 2nd.

Dogs' Protection Bill.

Sir F. Banbury moved the second reading of the Dogs' Protection Bill, a measure to prohibit vivisection experiments on dogs. He said that the Bill had three times received a second reading in that House, twice without opposition, and once by a majority; and on one occasion it passed committee and report stages and was only rejected on third reading. The only argument advanced against it was that it would do harm to medical research. Practically its only opponents were doctors. (Hon. Members, "No.") The majority were doctors. (Hon. Members, "No.") He might quote a short passage from The Lancet of May 31st, 1919, which said: "The memorandum of the Medical Research Committee, which we also print, demonstrates without reasonable gainsay that the experimental use of dogs has advanced our knowledge and been of benefit to suffering humanity. This is not to say that such knowledge could have been acquired in no other way." Therefore it was clear from the evidence of medical men that they could have acquired the knowledge which they said they had acquired in another way than by experimenting on dogs.

Mr. J. Jones said he desired to second the motion of his right hon. and dogmatic friend. (Laughter.)

Lieut.-Colonel Fremantle said that there was no time to advance a tithe of the arguments which rose to one's lips in speaking against this Bill. Sir F. Banbury had quoted but at the same time misread a passage from The Lancet. The Lancet did not say that such results as had been achieved from experiments on dogs could have been achieved in other ways. The Lancet was unable to say that these results could not have been achieved in other ways—which was an entirely different thing. The Lancet, as a matter of fact, said what they all agreed upon. Very often they might find experiments on other animals would give similar results in the long run, but the great point of medical research work was that when they started it in the laboratory they could not go directly to their end by the particular route they thought best; they had to spread their net as widely as possible in the hope that science would reveal herself with results that they could not anticipate. Among things that must be so revealed were different points which could only be revealed through experiments on dogs.

At this stage, it being 4 o'clock, the debate stood adjourned under the Standing Orders, and the Bill was accordingly "talked out."

Legitimacy Bill.

Mr. H. Betterton moved the second reading of the Legitimacy Bill, which he said provided that where the parents of an illegitimate child married one another before or after the passing of the Act, the marriage would render that person, if living, legitimate. The Bill would not legitimise a person whose father or mother had been married to a third party. It was an attempt to bring the law of this country into conformity not only with that of most civilised countries abroad, but also with that of Scotland.—Capt. Bowyer seconded.

Sir S. Russell-Wells opposed the measure.—Sir D. Hogg (Attorney-General) said the Government, while not hostile to the Bill, did not regard it as a party measure, and left it to the free vote of the House.—The second reading was carried without a division.

Monday, March 5th.

Training Centres for the Blind.

Mr. Graham White asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, the number of workshops, hostels, and training centres for blind persons which had been opened since the Blind Persons Act, 1920, came into operation.—Sir W. Joynson-Hicks replied: Since the Blind Persons Act, 1920, came into operation four new workshops have been opened and considerable extensions have been made to six existing workshops. One new hostel has been opened and one extended. Training centres are under the control of the Board of Education, but my right hon. friend is informed by that department that they have recognised eight new centres and four new hostels for training purposes.

Local Authorities and the Blind.

Mr. GRAHAM WHITE asked the Parliamentary Secretary to the Overseas Trade Department, as representing the Ministry of Health, the number of local authorities who had not submitted schemes for the exercise of their powers under the Blind Persons Act, 1920.—Sir W. JOYNSON-HICKS replied: The number of local authorities who have not submitted schemes for the exercise of their powers under the Blind Persons Act, 1920, is ten.

TUESDAY, MARCH 6TH.

Child's Death after Vaccination.

Mr. LUNN asked the Secretary of State for the Home Department whether he was aware that Mr. F. Scholefield, of Buckley-road, Beeston, Leeds, was ordered by the Leeds magistrate on Feb. 15th to have his child vaccinated; that the child for whom the order was made died from convulsions through teething on Feb. 24th: and whether he would instruct the magistrate who made the order to cancel it and abstain from asking for costs in this case.—Mr. BRIDGEMAN replied: I have no authority to give instructions of this nature to a magistrate. When a court has made an order imposing costs on a defendant, it is for the parties by whom the costs will otherwise be payable to decide whether they will press for the enforcement of this part of the order and for the court to decide whether it will enforce it. I have no power to interfere with the court's discretion in the matter.

Mothers' Pensions.

Mr. RHYS DAVIES called attention to the question of mothers' pensions; and moved, "That, in the opinion of this House, pensions adequate for the proper upbringing and maintenance of children should be paid to all widows with children or mothers whose family breadwinner has become incapacitated, such pensions to be provided by the State and administered by a committee of the municipal or county council wholly unconnected with the Poor-law."—Mr. LUNN seconded.

Mrs. WINTRINGHAM, in supporting the motion, urged that it could be carried out without any fresh machinery. Children under 5 could be dealt with at the welfare centres, and those between 5 and 14 by the educational authorities. None of the countries that had adopted mothers' pensions had repealed them. She understood that it cost 17*s.* 6*d.* for each child maintained under the Poor-law, and surely it would be better to give a widow 10*s.* a week for each child, and let her keep them at home. The future of the country as an A1 nation depended upon the health of the children.—Sir W. JOYNSON-HICKS, in opposing the motion on behalf of the Government, said that it would cost something between £45,000,000 and £50,000,000 a year, which the country could not afford at the present time.—The motion was rejected by 248 votes to 184.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, March 12th.

WAR: at 5 P.M.
Paper:
Colonel J. F. C. Fuller, D.S.O., p.s.c.: Problems of Future Warfare.
The Discussion will be opened from the medical standpoint by Lieut.-Colonel P. A. Anderson, R.A.M.C., to be followed by Lieut.-Colonel W. P. MacArthur, D.S.O., and others.
This meeting should be of particular interest and visitors are cordially invited.

Tuesday, March 13th.

THERAPEUTICS AND PHARMACOLOGY: at 4.30 P.M.
Discussion on the Action of Quinidine in Cases of Cardiac Disease.
To be opened by Prof. F. R. Fraser, followed by Dr. A. N. Drury, A. E. Clark-Kennedy, and Dr. T. F. Cotton.
GENERAL MEETING OF FELLOWS: at 5 P.M.
Paper:
Mr. J. E. Adams will read a paper on the Urgent Need for Education in the Control of Cancer.
A Discussion will follow, opened by Dr. C. P. Childe, Lord Dawson, Dr. Herbert Spencer, and others will also speak.
PSYCHIATRY: at 8.30 P.M.
Papers:
Dr. C. S. Myers: The Association of Psychoneuroses with Mental Deficiency.
Dr. H. J. Norman: Genius and Insanity.

Thursday, March 15th.

DERMATOLOGY: at 5 P.M. (Cases at 4.30 P.M.)
Cases:
Dr. E. Graham Little:
(1) Mycosis Fungoides;
(2) Folliculitis Ulerythematosa Reticulata;
(3) Lichen Planus of Unusual Distribution.
Dr. Bunch: Case of Premycosis.
Other cases will be shown.

Friday, March 16th.

OTOLOGY: at 5 P.M. (Cases at 4.45 P.M.)
Cases will be shown by Sir James Dundas-Grant, Mr. F. J. Cleminson, and others.
Papers:
Dr. F. M. R. Walshe: The Symptomatology of Eighth Nerve Tumours.
Mr. Wilfred Trotter: The Surgical Treatment of Tumours of the Eighth Nerve.
ELECTRO-THERAPEUTICS: at 8.30 P.M.
Paper:
Prof. Gosta Forsell (of Stockholm): Some Observations on Movements of Gastro-Intestinal Mucosa.
CLINICAL, MEDICINE, SURGERY.
Members of these Sections are cordially invited to attend the above meeting of the Section of Electro-Therapeutics.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, W.
MONDAY, March 12th.—8.30 P.M., Discussion on the Value of Laboratory Investigation in Diseases of the Liver (including Biliary System) and of the Pancreas, to be introduced by Dr. Langdon Brown, followed by Dr. Langmead, Dr. McKenzie Wallis, Dr. J. W. McNee, Dr. E. A. Dodds, Dr. G. A. Harrison, Mr. H. E. Griffiths, Dr. George Graham, Dr. C. M. Wilson, and others.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE.
THURSDAY, March 15th.—8.15 P.M., a Laboratory Meeting will be held at the R.A.M. College, Grosvenor-road, S.W.
Demonstrations will be given by Major E. E. Austen, Colonel A. Alcock and Lieut.-Colonel H. J. Walton, Drs. J. A. Arkwright and H. M. Woodcock, Dr. Broughton-Alcock, Dr. S. H. Daukes, Lieut.-Colonel S. P. James, Dr. J. G. C. Ledingham, Prof. R. P. Leiper, Dr. J. W. S. Macfie, Dr. H. B. G. Newham, Lieut.-Colonel H. Marrian Perry, Dr. A. C. Stevenson, and Dr. G. M. Vevers.

WEST KENT MEDICO-CHIRURGICAL SOCIETY, Miller General Hospital, Greenwich, S.E. 10.
FRIDAY, March 9th.—8.45 P.M., Dr. W. Langdon Brown: The Influence of the Endocrines in the Psychoneuroses.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.
TUESDAY, March 13th.—5 P.M., Third Goulstonian Lecture: Dr. G. Evans: The Nature of Arteriosclerosis.
THURSDAY.—5 P.M., First Lumleian Lecture:—Dr. A. J. Hall: Encephalitis Lethargica (Epidemic Encephalitis).

ROYAL COLLEGE OF SURGEONS OF ENGLAND, Lincoln's Inn Fields, W.C.
MONDAY, March 12th.—5 P.M., Hunterian Lectures on Man's Posture: its Evolution and Disorders: Prof. Sir A. Keith. Lecture IV.
WEDNESDAY.—5 P.M., Lecture V.
FRIDAY.—5 P.M., Lecture VI.

FELLOWSHIP OF MEDICINE, POST-GRADUATE LECTURES, 1, Wimpole-street, W.
WEDNESDAY, March 14th.—5.30 P.M., Mr. A. J. Walton: The Differential Diagnosis of Surgical Dyspepsias.

WEST END HOSPITAL FOR NERVOUS DISEASES.
The following Clinical Demonstrations will be held during the forthcoming week in the Out-patient Department of the Hospital, 73, Welbeck-street, W. The Demonstrations are open to Practitioners and Medical Students without fee.
WEDNESDAY, March 14th.—1.30 P.M., Dr. W. R. Reynell: Common Neuroses.
FRIDAY, March 16th.—5 P.M., Dr. Worster-Drought: Diagnosis of Cranial Nerve Lesions.
C. WORSTER-DROUGHT, M.D., Dean.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.
FRIDAY, March 16th.—4.30 P.M., Dr. Swift Joly: Demonstration of Urological Cases.

UNIVERSITY OF LONDON ADVANCED LECTURES IN MEDICINE, Robert Barnes Hall, Royal Society of Medicine, 1, Wimpole-street, W.
WEDNESDAY, March 14th.—5.30 P.M., Sir Archibald E. Garrod: Hæmatoporphyria Congenita (Congenital Porphyrinuria).

UNIVERSITY COLLEGE, Gower-street, W.C.
(Course of Three Public Lectures in the Physiology Theatre.)
WEDNESDAY, March 14th.—5 P.M., Mr. A. H. Drew: The Cultivation of Tissues in Vitro.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, POST-GRADUATE COURSE, Westmoreland-street, W.
THURSDAY, March 15th.—5.30 P.M., Sir Sydney Russell-Wells, M.P.: The Differences in the Circulation in Aortic and Mitral Disease.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.

POST-GRADUATE COURSE: Jan.–March, 1923.

Clinical Lectures and Demonstrations.

Monday, March 12th.—2 p.m., Out-patient Clinic: Dr. Hinds Howell. 3.30 p.m., Lecture:—Trauma in the Ætiology of Organic and Functional Nervous Diseases: Dr. Kinnier Wilson.

Tuesday, March 13th.—2 p.m., Out-patient Clinic: Dr. Grainger Stewart. 3.30 p.m., Lecture:—Disseminated Sclerosis: Dr. Hinds Howell.

Thursday, March 15th.—2 p.m., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 p.m., Lecture:—Electrical Treatment of Some Common Nervous Disorders: Dr. Bailey.

Friday, March 16th.—2 p.m., Out-patient Clinic: Dr. Gordon Holmes. 3.30 p.m., Lecture:—Compression Paraplegia: Mr. Sargent.

Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 a.m., or at such other times as may be announced.

Neuro-Pathology.

Monday, March 12th.—12 noon, Poliomyelitis and Encephalitis Lethargica: Dr. J. Godwin Greenfield.

N.B.—A Course of Lectures in the Anatomy and Physiology of the Nervous System will be given if there are sufficient entries for it.

The fee for the whole Course, including Anatomy and Physiology, is £12 12*s.*; but these Lectures may be taken separately for a fee of £4 4*s.* Course without Anatomy and Physiology Lectures will be £10 10*s.* Any part of the Course may be taken separately at a special fee. Special arrangements will be made for those unable to take the whole Course. Fees should be paid to the Secretary of the Hospital at the office on entering for the Course.

C. M. Hinds Howell, Dean of Medical School.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

Monday, March 12th.—10 a.m., Mr. MacDonald: Genito-Urinary Department. 12 noon, Mr. Simmonds: Applied Anatomy. 2 p.m., Mr. Addison: Surgical Wards.

Tuesday.—10 a.m., Dr. Patterson: Demonstration of Medical Cases. 12 noon, Dr. Burrell: Chest Cases. 2.30 p.m., Mr. Tyrrell Gray: Surgical Wards.

Wednesday.—11 a.m., Mr. Simson: Gynæcological Demonstration. 12 noon, Dr. Burnford: Pathological Demonstration. 4 p.m., Dr. Owen: Diagnosis of Medical Diseases of the Pancreas.

Thursday.—10 a.m., Dr. Grainger Stewart: Neurological Department. 12 noon, Mr, Simmonds: Demonstration of Fractures. 2 p.m., Mr. Bishop Harman: Eye Department.

Friday.—12 noon, Dr. Flett: Radiology. 2 p.m., Mr. Banks-Davis: Diseases of Throat, Nose, and Ear. 3 p.m., Mr. Sinclair: Surgical Cases.

Saturday.—9 a.m., Dr. Burnford: Bacterial Therapy. 10 a.m., Dr. Saunders: Medical Diseases of Children. 10.30 a.m., Mr. Maingot: Surgical Pathology.

Daily, 10 a.m. to 6 p.m., Saturdays, 10 a.m. to 1 p.m., In-patients, Out-patients, Operations, Special Departments.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street.

Thursday, March 15th.—4 p.m., Mr. Barrington Ward: After-Treatment of Operations.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.

Thursday, March 15th.—5 p.m., Dr. C. H. Roberts: Rupture of the Uterus.

MANCHESTER ROYAL INFIRMARY, POST-GRADUATE COURSES.

Tuesday, March 13th.—4.15 p.m., Mr. W. H. Hey: Jaundice from the Surgical Point of View.

Friday.—4.15 p.m., Mr. W. R. Douglas and Dr. J. M. W. Morison: The Diagnosis of the Surgical Treatment of Lesions of the Large Intestine.

SALFORD ROYAL HOSPITAL POST-GRADUATE LECTURE.

Thursday, March 15th.—4.30 p.m., Dr. Jenkins: The Bacteriology of Acute and Chronic Rheumatism.

THE INSTITUTION OF HEATING AND VENTILATING ENGINEERS, Engineers Club, Coventry-street, W.

Friday, March 9th.—7 p.m., Mr. J. G. Clark: Gas as a Fuel.

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.

Wednesday, March 14th.—4 p.m., Dr. J. H. Sequeira: Prevention of Congenital Syphilis.

Appointments.

Martin, A. A., M.D. Lond., B.S., M.R.C.S. Eng., D.P.H., has been appointed a Medical Referee under the Workmen's Compensation Act for County Court Circuit No. 50 (Eastbourne, Hastings, and Rye County Courts).

Mason, J. H., M.B., Ch.B.Vict., D.P.H., Assistant School Medical Officer, Northampton Borough Education Committee.

Coombe Hospital, Dublin: Douglas, Miss, L.R.C.P. & S.Irel., Clinical Research Assistant; Crighton, B., M.D. Dub., Infant Physician; Pepper, G. E., L.R.C.P. & S.Irel., in charge of the X Ray Department; and Cannon, D. J., M.B., B.Ch., B.A.O., in charge of Radium Department.

Dr. Steevens' Hospital, Dublin: Purser, F. C., M.D. Dub., Consulting Neurologist; Pepper, G. E., L.R.C.P. & S. Irel., Assistant Surgeon; O'Leary, Mary M., M.B. N.U.I., Anæsthetist.

Certifying Surgeons under the Factory and Workshop Acts: Beattie, W. F. (Stourbridge); Robertson, A., M.B., C.M. Edin. (Hornsea, East Riding).

Vacancies.

For further information refer to the advertisement columns.

Aberdeen Royal Infirmary Treatment Centre.—Jun. M.O. £500.

Ayr County Hospital.—Res. H.S. £175.

Barnet, Wellhouse Hospital.—Asst. Res. M.O. £150.

Bethnal Green Hospital, Cambridge-road, Bethnal Green, E.—Asst. Med. Supt. £500.

Birmingham Orthopædic Centre.—Jun. M.O. £350.

Bristol General Hospital.—Hon. Surg. Reg.

Bristol Royal Hospital for Sick Children and Women.—Hon. S. to Out-patients.

Burnley County Borough.—Asst. M.O.H., &c. £500.

Buxton, Devonshire Hospital.—Asst. H.P. £150.

Carlisle, Cumberland Infirmary.—R.M.O. £175.

Colchester, Severalls Mental Hospital.—M.O. Locum Tenens. 7 guineas weekly.

Durham County Education Committee.—Asst. Oculist. £600.

Eastbourne, Princess Alice Memorial Hospital.—Hon. M.O. for Radiological and Electro-Therapeutic Department.

Elizabeth Garrett Anderson Hospital, Euston-road.—Asst. M.O. £1 1*s.* per attendance. Also Asst. P. to Out-patients.

Halifax Royal Infirmary.—Third H.S. £150.

Inverness District Asylum.—Jun. Asst. M.O. £250.

Leicester City.—R.M.O. £350.

Liverpool Eye and Ear Infirmary.—H.S.

London Fever Hospital, Islington, N.—Hon. Aural S.

London Lock Hospital, 91, *Dean-street, W.*—H.S. £200.

Manchester City.—Female M.O. £632 7*s.* 8*d.*

Portsmouth Child Welfare Centres and Municipal Maternity Hospital.—M.O. £500.

Queen Charlotte's Lying-in Hospital, Marylebone-road, N.W.—Two Asst. Res. M.O.'s. £80.

Rotherham Hospital.—Jun. H.S. £150.

Royal Chest Hospital, City-road, E.C.—Res. M.O. £200. Also H.P. £120.

Royal National Orthopædic Hospital, 234, *Great Portland-street, W.*—H.S. £150.

Royal Northern Hospital, Holloway-road, N.—Surgeon for Diseases of Ear, &c.

St. Mary's Hospital for Women and Children, Plaistow, E.—Res. M.O. £175.

St. Peter's Hospital for Stone, Henrietta-street, Covent Garden, W.C.—H.S. £75.

Salford Royal Hospital.—H.P. £200. H.S. and Cas H.S. £150 each.

Seamen's Hospital Society, Dreadnought Hospital, Greenwich, S.E.—H.S. £150.

Sheffield, South Yorkshire Asylum.—M.O. £400.

South London Hospital for Women, Clapham Common, S.W.—H.P. £100.

South Shields, Ingham Infirmary.—Jun. H.S. £150.

Sunderland Royal Infirmary.—H.S. £160.

Truro, Royal Cornwall Infirmary.—H.S. £170.

University College Hospital, Gower-street, W.C.—Clin. Asst. for Ear, Nose, and Throat Dept.

University College Hospital Medical School, University-street, W.C.—Asst. to Professor of Pathology. £500.

West Derby Union, Brownlow Hill Institution.—Asst. Res. M.O. £300.

West End Hospital for Nervous Diseases, Regent's Park, N.W.—Jun. H.P. £100.

Western Ophthalmic Hospital, Marylebone-road, N.W.—First and Second H.S.'s. £150.

West London Hospital, Hammersmith-road, W.—H.P. and Two H.S.'s. Each £100.

Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

Births, Marriages, and Deaths.

BIRTHS.

Hincks.—On Feb. 28th, at Sunny Mead, Wells, Somerset, the wife of Dr. A. C. Hincks, M.C., of a son.

Loughlin.—On March 3rd, at Swaffham, Norfolk, the wife of D. Loughlin, M.R.C.S., L.R.C.P., of a daughter.

Robinson.—On Feb. 10th, at 23 b, Manchester-road, Southport, to the wife of John Hargreaves Robinson—a son (by induction).

Ross.—On March 1st, at Westacre, Sleepers Hill, Winchester, the wife of E. Athole Ross, M.D., M.R.C.P., of a son.

Weston.—On Feb. 27th, at East Ascent, St. Leonards-on-Sea, the wife of Dr. H. J. Weston, of a son.

MARRIAGES.

Browne—Thomson.—On March 6th, at St. Hildeburgh's, Hoylake, by the Rev. W. T. Warburton, Hablot Browne, M.D., of Hoylake, to Dora Thomson, of Wath on Dearne, Yorks.

DEATHS.

Hardyman.—On Feb. 27th, Dr. Hardyman, Hill House, Bramerton, nr. Norwich, aged 75.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

REFLECTIONS ON HIGH BLOOD PRESSURE.*

BY SIR HUMPHRY ROLLESTON, K.C.B., M.D., D.C.L., LL.D.,
PRESIDENT OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON ; EMERITUS PHYSICIAN, ST. GEORGE'S HOSPITAL, LONDON.

ALTHOUGH von Basch of Vienna invented his sphygmomanometer in 1881, it is only within the present century that its use has become familiar in medical practice. An important milestone in the history of blood pressures was Korotkoff's description in 1905 of the auscultatory method which renders the estimation of the diastolic pressure as easy as that of the systolic pressure. The period of *réclame* when a high blood pressure was the signal for measures to bring it down at all costs is passed.

It is important to get a true perspective of the value of blood-pressure estimations ; there is a certain amount of personal variation in different individuals, and the actual height of the blood pressure must be regarded as but one out of several manifestations that have to be taken into account, and not as the only one of importance. It is advisable not to inform the patient exactly what his blood pressure is, as this may lay up a store of future anxiety ; and blood-pressure estimations should not be made frequently. On the other hand, the discovery of a high blood pressure in its early stage before the onset of secondary and structural changes has a great prophylactic value as it thus enables further progress to be counteracted. There is, therefore, much to be said from the point of view of preventive medicine in advising people of 40 years of age and over to have their blood pressure recorded every six months or so in order that their manner of life may, if necessary, be modified. Just as most sensible people pay periodic visits to the dentist to see if any change has taken place in their teeth, so a fortiori should they take a stitch in time as regards the infinitely more important cardiovascular system. Slight differences in pressures taken at different times must not be regarded as important. Not only must transient variations in the patient, such as are due to excitement, be taken into account, but also the personal equation of the examiner depending on his acuity of sense or touch in feeling the pulse or of hearing when employing the auscultatory method. A difference of 10 to 15 mm. in the systolic pressure should not necessarily be regarded as of any significance in one's own reading, and this reservation should be more liberal in comparing the readings recorded by different observers. It is thus clear that undue importance may be attached to an isolated examination of the blood pressure, especially if that is taken by a stranger in imposing and anxious circumstances.

It has been objected that clinical sphygmomanometry cannot accurately represent the intra-arterial pressure on account of the interference exerted by the condition of the arterial walls, arteriosclerosis, calcification, and spasmodic contraction, and by the amount of intervening—muscular and fatty—tissue. As regards arteriosclerosis it has been found that the rise due to this cause, even when calcification has occurred, is not more than 10 to 15 mm. (Janeway and Park). The effect of spasmodic contraction in raising the resistance to the compressing force exerted by the cuff and so increasing the apparent blood pressure has been much insisted on by Prof. William Russell ; as a rule the local tonus can be made to disappear by repeated compression of the artery. This is another reason for taking several readings at each examination.

Normal Blood Pressure.

The blood pressure gradually rises from birth when the systolic pressure has been stated to be 35 to 55 mm.Hg. As a rough rule for arriving at the healthy systolic pressure for a man's age (a woman's must be taken at 10 mm. or so lower) I am accustomed to add 100 to the age and to consider this as the maximum systolic pressure which should not cause anxiety, and to regard 100 plus half the age as the most satisfactory healthy systolic pressure ; thus, for a man of 40 years of age a systolic pressure between 140 and 120 may be regarded as within the normal limits. Very possibly these limits are too narrow. The diastolic pressure may be taken as three-quarters of the systolic pressure up to middle life, but after this and in old age, from the frequency of rigid arteries it falls and may be only half the systolic pressure.

It must not be forgotten that blood pressure is subject to certain physiological and racial variations.

Difference of the blood pressure in the two arms may be due to various factors, physiological or pathological, and so be either unimportant or significant. A physiological explanation is that the first reading taken is often emotionally high and that by the time the other arm is examined the normal level has been approached. A difference on the two sides may depend on anatomical abnormalities in the size and distribution of the blood-vessels in the upper limbs. Of pathological significance are differences on the two sides due to arteriosclerosis more advanced at the orifice of the innominate or of the left subclavian, an aortic or other aneurysm, an intrathoracic tumour, or a cervical rib. It is not infrequent in hemiplegia and, according to Dana, suggests that the optic thalamus is damaged.

The Effect of Tobacco Smoking on Blood Pressure.—From a pharmacological point of view nicotine has a very powerful pressor effect, but this is in doses much larger than are usually absorbed in man. Tobaccos vary considerably in their nicotine content. The immediate effect of smoking is to raise the systolic pressure from 5 to 25 mm. Hg, the diastolic being much less affected. At the same time the pulse-rate is increased. But in a short time the blood pressure falls to normal or even below normal. It is generally agreed that confirmed smokers have a low blood pressure. As age advances and as arteriosclerosis becomes more frequent, tolerance for tobacco becomes less.

High Blood Pressure.

Sex Incidence.—Males are more often the subject of high blood pressure than females. It is interesting to note that according to some hypotheses of high blood pressure the female sex should be much more prone to this condition than is really the case ; for women are more subject than men to constipation and to hypothyroidism.

Heredity undoubtedly plays a part in the production of high blood pressure, and measures can thus be adopted to counteract a known tendency. It is commonly stated that high arterial blood pressure and its common result arteriosclerosis are much more frequent in these strenuous hustling times than in the more spacious past ; before the introduction of the sphygmomanometer, however, very many cases must have remained unrecognised.

The relation between high blood pressure and arteriosclerosis established by Sir Clifford Allbutt is as follows : (1) High blood pressure often precedes the appearance of arteriosclerosis which may then be called hyperpietic arteriosclerosis. (2) Arteriosclerosis is not invariably of this nature but may be due to toxic or infective agents, of which syphilis is a well-known example. (3) Though arteriosclerosis does not cause a high blood pressure, the two conditions are often associated.

Ætiology.—In discussing the ætiological factors of continued high blood pressure a division into two separate groups is convenient : (1) Cases in which nephritis, acute, subacute, or chronic, has undoubtedly preceded the advent of high blood pressure. (2) Cases in which there is no evidence of renal disease before or in the early stages of the high blood pressure. This form of high pressure was sometimes spoken of as essential, primary, or benign hypertension. Sir Clifford Allbutt introduced the name of hyperpiesia. While welcoming a sharp cut distinction between the primary renal and non-renal cases, it must be admitted that, apart from the assistance of tests for renal efficiency, it is difficult to be certain in cases of high blood pressure that early renal change is not present and, indeed, perhaps playing its part by the production of some pressor substance, in the maintenance of the hypertension (H. B. Shaw). A diagnosis between pure hypertension and renal high blood pressure is, however, important both from the point of view of prognosis and of treatment, and in arriving at such a diagnosis the quantitative examination of the non-protein nitrogen of the blood is invaluable.

In *essential high blood pressure or hyperpiesia* the causal factor, though it need not be the same as in renal disease, might well be a somewhat similar pressor body. An obvious suggestion is that in different instances different bodies or poisons are responsible.

It must be admitted that of the cause or causes of simple permanent high blood pressure we really have no exact knowledge. It is difficult to disagree with Batty Shaw's view that the cause is toxæmia, but as the toxins are unknown, it is for practical purposes essential to act on the data we have as to the antecedent conditions that appear to play a casual part ; they are excess of protein food, worry, and diseases and conditions of environment which upset normal metabolism, one of the ways being by inducing disorder of the glands of internal secretion. It would be interesting to know how long high blood pressure takes to develop. That nervous excitement will raise it in a few minutes is familiar, and that acute nephritis will rapidly bring it about is certain. The question requiring an answer is how long as a rule does the persistent rise of blood pressure take to be evolved in cases without preceding renal change? It generally appears to be a slowly advancing process of many years' duration, but is it not sometimes relatively acute?

---

* Abstract of the annual address, delivered before the Newcastle-upon-Tyne and Northern Counties Medical Society.

Clinical Features.

In considering the clinical manifestations of high blood pressure it is important to bear in mind the distinction between those that are associated with increased blood pressure only and those that result from concomitant or secondary disease of the vascular or other systems. Thus arteriosclerosis with cerebral hæmorrhage or thrombosis and arteriosclerotic atrophy of the kidneys with uræmia are the late secondary or end-results of continued high blood pressure. Failure of the compensatory cardiac hypertrophy should be regarded in a similar light to arteriosclerosis, and as a late result of long sustained high blood pressure, which might never have occurred had hyperpiesia been recognised and counteracted in its early stages. In practice it is essential to grasp the different significance to be attached to high blood pressure (*a*) when not accompanied by evidence of arterial disease, and (*b*) when so complicated. Thus cerebral hæmorrhage is not likely to supervene as long as the arterial system remains healthy. Clinically, however, it is unsafe to say that because the vessels sufficiently superficial to be palpable are healthy, there is not some arteriosclerosis of the cerebral, coronary, or mesenteric vessels, though ophthalmoscopic examination of the fundi may help by showing the characteristic silver wire arteries of arteriosclerosis.

Latency.

High blood pressure is quite commonly found in vigorous persons who are unconscious of any disability; thus Külbs found that among 288 persons (172 males, 116 females) with a systolic blood pressure of 170 mm. or more there were 20 per cent. without any symptoms; we must therefore recognise that high blood pressure may be in some respects, and for some time at least, a beneficent process which compensates for some disorder of function: just as according to Thoma arteriosclerosis is originally a compensatory mechanism to prevent dilatation at the site of weakness of the muscular media. Here we have two compensatory medianisms which frequently fail and finally become pathological. What the compensatory effect of high blood pressure is we do not know; possibly it may have several functions, just as it appears to have several causes. As the velocity of the blood-stream rises with the increase of blood pressure, the necessity for a more efficient blood-supply to the tissues or for purposes of efficient elimination may be an explanation. The absence of symptoms in some cases of high blood pressure would appear to show that though something is wrong compensation has been established for the time being, whatever may happen in the future. In fat people high blood pressure is often present and frequently latent (Aubertin and Coursier). In latent high blood pressure the physical signs are the sphygmomanometer readings, the sensation conveyed to the examining finger by the pulse, and in permanent high blood pressure of some duration hypertrophy of the heart and accentuation of the second sound over the aortic area. The blood pressure in the capillaries is low (Boas and Frant). It has been stated that oscillation of the leg when the corresponding knee is crossed over the other shows that the blood pressure is over 160 mm. Hg (Molle); this phenomenon, so familiar in aortic incompetence, would appear to depend on a large pulse pressure which is a result of rigid vessels and not necessarily associated with a very high systolic pressure. A more important sign of high blood pressure, though due to accidental circumstances, such as an angioma or an ulcer in the nasal passages, is epistaxis. This may be the first indication of abnormally high pressure in a vigorous man quite free from any feeling of illness, and the information that he is the subject of high blood pressure may come like a bolt from the blue.

Remarks on High Blood Pressure in Cardiac Affections.

In cardiac disease high blood pressure is mainly of interest in (1) the distinction of primary from secondary cardiac failure, and (2) in connexion with aortic regurgitation. In primary myocardial insufficiency and in primary mitral disease the systolic blood pressure is not, as might be expected, considerably below normal but is well maintained (H. J. Starling). In cases of secondary cardiac failure due to high blood pressure the elevated systolic pressure reveals the cause. The blood pressure in mitral stenosis varies in different cases; whereas in cases with healthy kidneys it is normal or slightly raised there is a group of cases in which mitral stenosis is associated with, if not secondary to, renal fibrosis (Pitt, Cowan and Fleming), and it is not unlikely that syphilis may cause both mitral stenosis and granular kidney; in such cases the blood pressure may be very considerably raised. In aortic regurgitation the pulse pressure is large, though in some cases the thud ordinarily heard over the arteries in this form of valvular disease makes it difficult to determine the diastolic pressure by the auscultatory method. Leonard Hill, Flack, and others have shown that in aortic regurgitation there is a well marked difference between the systolic pressure in the arm and in leg when the patient is lying down, being much higher in the leg. This difference is also found in abdominal aortitis (Heitz, Gallavardin), in arteriosclerosis, and in high blood pressure. It is not due to the regurgitation of blood into the ventricle, but to the condition of the vessels.

The Prognostic Value of Blood Pressure in Acute Disease.

In most acute infections the blood pressure is lowered. Diphtheria shows a well marked fall of blood pressure; in scarlet fever the lowering of pressure is much less than in diphtheria and enteric fever. The behaviour of the blood pressure in pneumonia has aroused considerable interest. The late G. A. Gibson formulated an attractively worded dictum that when the arterial pressure, expressed in millimetres of mercury, does not fall below the pulse-rate, expressed in beats per minute, the fact may be taken as of excellent augury, while the converse is equally true. This law has naturally been investigated, and it appears that the important factor in its prognostic bearing is the pulse-rate and not the maintenance of a blood pressure near the normal. Newburgh and Minot in America and Geoffrey Evans in this country found that the blood pressure was higher in the fatal than in the surviving cases of pneumonia. Tuberculosis is generally regarded as characterised by a low blood pressure. In syphilis the blood pressure is not necessarily raised. Secondary syphilitic changes in the endocrine glands and the widespread lesions of congenital syphilis, of which granular kidney may be one, may lead to a high blood pressure. It appears that though recent syphilitic infection does not raise the blood pressure, its protean effects may do so. When this occurs the special arterial lesions will increase the liability to cerebral hæmorrhage.

Prognosis.

Many patients live for years although their systolic blood pressure is 200 mm. and diastolic 120 mm. But as the statistics of life insurance companies and others show, the mortality of individual with systolic pressures over 160 mm. is much above the average; de Havilland Hall in private practice saw 125 patients with systolic blood pressure under 160 mm., and 5 deaths, or 3 per cent., and 48 patients with pressures over 160 mm., and 19 deaths, or 39·6 per cent. But within limits the actual height of the systolic blood pressure is not so important as the relation between the raised systolic and diastolic pressures. A high diastolic pressure, so that the pulse pressure is small, is the more serious condition as it is likely to be associated with granular kidney and carries with it the danger of cerebral hæmorrhage or uræmia. These cases may benefit from dietetic and purgative treatment. A high systolic pressure with a diastolic pressure relatively low, so that there is a large pulse pressure, is prone to lead to cardiac failure, and does not appear to react to dietetic restrictions, though digitalis helps them for a time. A steadily rising pressure is of worse prognosis than a stationary one, but a sudden fall of blood pressure is a cause for anxiety, as this is very probably due to cardiac failure. With regard to the prognosis of high blood pressure and the danger of cerebral hæmorrhage, it is well to bear in mind G. W. Norris's conservative statement that less than 15 per cent. of patients with a blood pressure of 200 mm. or above die from this cause, and that cerebral hæmorrhage may occur in patients whose blood pressure has not been known to be above 170 mm. Dyspnœa in a patient with hyperpiesia is a sign that the disease has advanced more than might otherwise be obvious; transient paralysis and slight strokes are very ominous, for it is often difficult to be sure that cerebral arteriosclerosis and minute hæmorrhages or focal degenerations are not in reality responsible, instead of simple spasm of a cerebral artery.

Treatment.

As high blood pressure is a sign of some underlying disorder or toxæmia, and is possibly to some extent a compensatory process, it is unwise to treat it simply by vasodilators and cardiac depressants. Vasodilators are probably useful in the crisis of high blood pressure, but none the less the essential indication is to deal with the conditions that may have a causal influence—namely, over-eating, worry, and toxæmia. The object at first should not be so much to reduce the blood pressure as to prevent any further rise. Over-eating and drinking, meat except in great moderation, meat extracts, strong coffee and tea, alcohol except in great dilution, and salt should be forbidden. As regards purins there is some difference of opinion, but it is safer to discountenance any but a very modest use of them. The intake of fluids should also be restricted. Rest in bed is useful when the heart is showing signs of stress, and usually brings the blood pressure down, but when the period of bed is over the blood pressure often rises to much the same elevation as before. Patients with high blood pressure should be encouraged to take moderate exercise according to their ability, and if this be difficult to obtain, massage may be substituted. It is important to obtain distraction from worries and anxieties by the cultivation of hobbies, golf, travel, and visits to spas. The easy advice to avoid worry is often a difficult prescription to dispense, but small doses of bromides may be useful in making the patients more philosophic, less sensitive and irritable, and so less prone to react to mental pinpricks.

As regards drugs there is no single panacea. Of purgative and antiseptic drugs to minimise intestinal stasis and putrefaction calomel has a high repute; minute doses (1/20 gr.) of calomel exert an antiseptic without, of course, any purgative effect. Of the nitrite and allied preparations sodium nitrite and erythrol tetranitrate have a more prolonged effect than trinitrin; and mannitol nitrate has an even more lasting effect than erythrol tetranitrate. In some cases a tablet of trinitrin helps the patient to sleep. As to the effect of iodides much has been written; clinical experience is in its favour. Hippurates and guipsin have been recommended, but have not inspired widespread confidence. The rise of blood pressure occurring at the menopause has been thought to be relieved by the administration of corpus luteum, especially by the hypodermic route (Osborne).

As to the effects of high-frequency currents Ronneaux and Lacquerriere, after an experience of 25 years, state that high-frequency currents have not any lasting effects as regards lowering the blood pressure in patients with a constantly raised blood pressure; but, nevertheless, its use reduces some of the minor symptoms, such as headache, giddiness, sleeplessness, and cold hands. As regards the administration of digitalis, now that it is recognised that digitalis does not raise the blood pressure in man, it may safely be given to persons with high blood pressure when indicated.

THE EARLY SPREAD OF JENNER'S TEACHINGS.

THE Royal Jennerian Society was founded in 1802 to spread the doctrines of vaccination, Edward Jenner being the first president. At the same time, or somewhat earlier, there had been established what was known as the Original Vaccine Pock Institution, having its headquarters in Broad-street, Golden-square, and intended as a distributor of "vaccine pock matter" or vaccine. A correspondent sends us the following interesting note on the proceedings of the two societies:—

"The Royal Jennerian Society for the Extermination of the Small Pox held its annual general court at the Central House, No. 14, Salisbury-court, on Wednesday, the 7th of March, 1804, and the Report of the Board of Directors and Medical Council then stated that 5987 persons had been inoculated under the auspices of the society and that over 6000 charges of vaccine matter had been issued from the Central House alone to every part of the Empire and of the world. The report expressed 'a confidence that such a foundation was laid as to afford a reasonable hope of gradually accomplishing the Extermination of the Small Pox.' Funds, however, were needed, and on the motion of Messrs. William Wilberforce and John Julius Angerstein it was agreed that the 'slumbering philanthropy' of the public should be appealed to in a practical manner. At the same time the Duke of Bedford was thanked 'for his Grace's condescending attention as Chairman,' and it was announced that a number of life governors, including Benjamin Travers, an important figure at the Royal College of Surgeons of England, had already subscribed from 1 to 5 guineas each. In May came the meeting and report of the Original Cow Pock Institution, when Lord Petre, chairman, explained 'that there was a register of observations made twice a week for 230 weeks, viz., from January, 1800; that the number of subjects inoculated, i.e., 2000, did not constitute the principal utility of the Institution, but the long-continued, uninterrupted observation nowhere else to be found. That it appeared that above 12,000 parcels of matter had been furnished to the public, and it was fairly estimated that not fewer than 60,000 persons had been 'vaccinated,' directly or indirectly, from the Institution. Deaths from small-pox had in 1804 sunk in Great Britain to 622, as compared with the average of 2018 annually in the latter half of the eighteenth century. This good result was doubtless greatly owing to the pioneer work of these two societies, connected as they were with those public benefactors, the Wilberforces, Angersteins, and Heavisides.

"In 1808 the Royal Jennerian Society ceased to exist, for, curiously enough, it had lost touch with Jenner's teachings and the Chief Resident Inoculator had set himself up as an authority in opposition. Jenner accordingly spent five months in London founding and organising the National Vaccine Establishment, which in time became the National Vaccine Institute. The report of the establishment in 1812 had become a State paper, which, after referring to the distribution of 23,794 charges of vaccine lymph in London alone in 1811, goes on to give interesting particulars as to the spread of vaccination in the navy, army, the British Isles, Ireland, India—small-pox had already disappeared in Ceylon—in the Dominions, and in Italy and Germany. The old-fashioned practice of inoculation, however, was still a source of public danger. 'It is much to be lamented,' says the report, 'that there are still some Medical Practitioners who obstinately persist in disseminating by inoculation the contagion of the Small Pox, and who strenuously encourage and support, especially among the lower orders of the people, the prejudice against the new practice.' The contagion is thus constantly kept up, and inoculation 'where it saves a single life, exposes numbers to a most dangerous disease.'

"Jenner would seem to have succeeded completely outside the British Empire. Napoleon could refuse nothing to his name. In Switzerland and Geneva the clergy preached vaccination, and the Chinese published his work on the cow-pox inoculation in their own language. From the East the chorus of praise of Jenner has not diminished. Of late years Prince Malcolm Khan, son of the famous Persian stateman, when on a visit under the guidance of the late Mr. Reginald Harrison to the library of the Royal College of Surgeons, asked first to be shown Edward Jenner's lancets. As he held in his hand the particular ones with which George Jenner, of the Vaccine Establishment, performed the earlier vaccinations, the turbaned ex-Etonian spoke feelingly of the manner in which whole Asiatic countries had been rescued by the teachings of Jenner from a scourge more terrible in the East than ever it was in Europe."

COLONIAL HEALTH REPORTS.

Basutoland.—From the annual report signed by Mr. R. B. Smith, Government Secretary, it appears that in 1921 typhus fever was prevalent; the number of cases and the death-rate being approximately the same as in the previous year (503 cases, 93 deaths); influenza, though very prevalent, was trivial in character (963 cases with 2 deaths). Pneumonia of a mild type has been noted, with only 2 deaths out of 79 cases reported. There were 187 cases of dysentery with 11 deaths. The cases of small-pox reached a total of 521, principally in the district of Leribe, with 53 deaths. Varicella was often observed, and in the native races it is frequently mistaken for small-pox by unpractised observers. In connexion with the infectious diseases mentioned it is worthy of note that in the district most remote from contact with European centres—viz., Qacha's Nek—there were but few cases of any kind. Steps were taken during the year in regard to the prevalence of syphilis. All cases of that disease now receive free treatment, and depôts have been established for the distribution of antisyphilitic remedies. This action has been greatly appreciated by the natives. In the leper settlement there were on Dec. 31st, 1921, 491 patients—229 males and 262 females—showing an increase of 77 over the number resident on the same date in 1920. The desertions during the year numbered 41. There were only 25 deaths, the smallest on record since the opening of the institution; 14 patients were discharged as arrested cases, and this result is in no small measure due to the success of the sodium morrhuate treatment adopted by Dr. Slack, the medical officer. A beginning has also been made with the treatment of leprosy by the ethyl esters of the chaulmoogric acids, but it has not been in use long enough for an opinion as to its efficiency to be given; 232 patients passed through the hospitals during the year, most of them suffering from cellulitis, ulcers, or other tropic lesions of leprosy.

Fiji.—The Hon. T. E. Fell, C.M.G., Colonial Secretary, in his report for 1921 remarks that the climate is exceptionally healthy. Malarial fever, the curse of so many tropical countries, is entirely absent, and the anopheles mosquito is not found in any island of the group. Europeans live to advanced ages and children thrive. Many Europeans, with their families, have resided in Fiji for prolonged periods without apparent damage to their vitality or constitution. The most prevalent diseases of a serious nature are dysentery and typhoid fever. Infection is generally fly-borne rather than water-borne. The drier climate of the north and west sides of Vitilevu was formerly badly infested with flies when both these diseases were prevalent, as was also ophthalmia in that locality. Within the last ten years flies have almost disappeared, and these diseases have now become rare. A similar improvement has occurred in Suva, on the wet side of the island, as a result of an efficient sewerage system; but in the rest of the most rainy zone cases of dysentery and enteric fevers are, unfortunately, not infrequent. Search has been made for a fly parasite. Large numbers of fly pupæ in manure are devoured by ants. A small wasp has recently been found by Dr. Carment, M.O.H., and Mr. H. Simmons, Government entomologist, as a common parasite of fly pupæ. It is hoped that this parasite may reduce fly infestation, but whether it has been the chief cause of the disappearance of flies on the dry side is not yet determined. A renewed effort is being made by the Government and the Rockefeller Foundation to reduce the high rate of infection amongst the Fijian and Indian population with ankylostomiasis. Sanitary measures are insisted on and carbon tetrachloride, a new anthelmintic (non-toxic, efficient, and cheap) is being administered to the people. The results up to now are promising, but several years' work will be necessary to stamp out the disease, so common in all tropical colonies. Education, through native medical practitioners and other means, is modifying the native view as to the desirability of infection of children with yaws. The salvarsan group of drugs is much sought after, and, if funds allow, it is now practicable to consider the eradication of a disease almost as deadly in its after-effects as syphilis is elsewhere. The method of intravenous injection of chaulmoogra oil for leprosy is being steadily improved by Dr. Harper, medical superintendent of the Makogai Leper Asylum. As far as the evidence yet goes permanent cure may result in favourable cases from its use. The proposal to erect a Memorial Hospital in Suva, and to establish cottage hospitals in outlying centres, in memory of those from Fiji who gave their lives in the late war, received enthusiastic support of the public and the necessary funds were readily forthcoming. The levelling of a site for the main hospital at Suva is being proceeded with. The building, estimated to cost £40,000, will be erected in ferro-concrete and will provide accommodation for 102 patients. A census of the population was taken in April, and showed 157,266 persons to be resident in the colony—viz., Europeans, 3878; half-castes, 2781; Fijians, 84,475; Indians, 60,634; Chinese, 910; others, 4588. The most gratifying features of the census are the figures showing that the decline of the Fijian race has been arrested, and that the disparity in the numbers of sexes of the Indian community is rapidly disappearing. The total rainfall recorded at Suva during 1921 was 170·74 inches, or 56·19 above the average. The average temperature for the year at Suva was 77° F.

A UNIQUE ATHLETIC ACHIEVEMENT.

A MEDICAL correspondent writes from Vienna as follows:—"Medical circles have recently been astonished and diverted by the extraordinary muscular strength of an athlete of Jewish extraction, Breitbart by name. This phenomenon is 34 years old, 190 cm. (6 ft. 3 in.) in height, and weighs 95 kg. (a little under 15 st.). His muscles are remarkably developed, particularly the biceps and forearm, chest, and thigh muscles; he is also very handsome and well built. He can easily bend iron rods into horse-shoes, or twist them into corkscrew shapes; he can bite through an iron or steel chain a fifth of an inch thick, lift huge weights, or place an anvil on his chest and allow iron to be hammered on it. A committee of experts—physicians, engineers, smiths, and presidents of athletic corporations—recently investigated his abilities, as the credibility of his feats was doubted, and as a girl of 19 years also claimed to be able, under hypnotic influence, to accomplish similar feats. The committee first examined the girl who, it was alleged, could perform these tasks only under hypnosis. She was able to bend and twist iron rods about one-third of an inch thick, but her strength was regarded as nothing extraordinary, some of the committee also being able to perform her feats, and no necessity for calling hypnotic or supernatural forces into play was recognised, it being merely a matter of training. With the 'modern Samson' it is an entirely different thing. Whilst, for instance, the normal pressure of a masticating molar tooth is about 25 kg., to bite through a steel chain requires immense force. Exact examination proved that the athlete accomplished this feat upon several chains, more by torsion of the link than by actual biting. He was then given rods of iron, about half an inch square, 2 metres long, which he bent into a circle by quick pressure of his hands, using the mouth as a fulcrum. This circle he then bent further into a spiral by pulling one end across the other. Here he used not only the arms, but also the pressure of the body, thus bringing into action first the scapular, supra- and infra-spinal and pectoral muscles, afterwards the abdominal muscles, together with the biceps and the forearm muscles. Pressure by the latter was measured and found to amount to 120 kg. in this experiment. In bending short, broad (1½ in.) hoops into a horse-shoe, he used his quadriceps cruris as a fulcrum, then exerted pressure by means of the adductor muscles of the thigh, placing his hands between his knees. The most remarkable achievement, however, is the following: A rail 10 metres long, 10 cm. (4 in.) thick, and 6 cm. (2½ in.) broad is placed on top of his head. A dozen people hang on to each side of this rail and try to bend it over his head. With a quick short jerk the athlete succeeds in bending it. Other feats, as lying flat on a bed of nails about ½ an inch apart, with their points up, are not extraordinary, but he is able to drive with a single stroke of his fist without a hammer, a nail completely into a board 1 in. thick after first biting off the point of the nail. The feats have been demonstrated so often and so uniformly to experts that there is no trace of a doubt left. The committee are satisfied that he accomplishes these tasks by means of extraordinary muscular power, coupled with excellent scientific training and exceptional muscular synergy."

EXPORTS OF MORPHINE AND ITS SALTS.

IN last week's issue of THE LANCET (p. 468) we published a statement by the Home Secretary showing the quantity of morphine and its salts registered as exported from the United Kingdom during 1920. Below will be found the figures for 1921, distinguishing the countries of destination prepared from returns rendered by exporters licensed under the Dangerous Drugs Act, 1920, to the Home Office.

Europe.	Amount in oz.
Austria	976·0
Belgium	2,711·8
Channel Islands	26·47
Czecho-Slovakia	2,046·12
Denmark	1,409·08
Esthonia	1·76
Finland	370·34
France	36,007·33
Germany	3,600·39
Gibraltar	4·09
Greece	40·64
Holland	1,134·58
Italy	6,742·19
Malta	26·41
Monaco	0·03
Poland	353·06
Portugal	149·91
Russia	4·0
Spain	4,775·19
Sweden	0·76
Switzerland	9·49
	60,389·64

Asia.	Amount in oz.
Aden	1·12
Arabia	1·84
British North Borneo	21·0
Ceylon	87·72
China	1,101·41
Cyprus	5·29
Dutch East Indies	71·34
Federated Malay States	180·73
Goa	1·04
Hong-Kong	60·4
India	1,319·79
Japan (Korea)	320·07
Mesopotamia	32·22
Palestine	11·14
Persia	117·76
Siam	52·56
Siberia	388·01
Straits Settlements	27·32
Syria	78·1
Turkey	1·22
	3,880·08

Africa.	Amount in oz.
Algeria	4·52
Angola	0·43
Basutoland	2·28
Congo Belge	4·71
Egypt	340·34
Gold Coast Colony	10·92
Kenya Colony	14·91
Liberia	0·08
Madagascar	0·15
Mauritius	27·88
Morocco	0·09
Nigeria	19·67
Nyasaland	0·43
Rhodesia	27·23
St. Helena	0·08
Sierra Leone	4·76
Sudan	48·47
Swaziland	1·18
Tanganyika Territory	18·19
Uganda	1·56
Union of South Africa	707·89
	1.235·77

America.	Amount in oz.
Argentine	865·37
Bolivia	1·06
Brazil	226·35
British Guiana	345·47
British West Indies	809·83
Canada	6,377·08
Chile	95·06
Dutch Guiana	14·42
Falkland Islands	0·16
Guatemala	112·0
Mexico	35·27
Nicaragua	0·16
Peru	30·86
Salvador	15·32
Uruguay	53·48
	8,981·89

Australasia.	Amount in oz.
Fiji Islands	0·06
New South Wales	871·59
New Zealand	700·96
Queensland	58·43
South Australia	677·24
Tasmania	28·0
Victoria	348·12
Western Australia	192·71
	2,877·1
Grand total	77,364·48

1. These figures do not include heroin and salts of heroin.
2. These figures *include* exports by parcel post and the morphine and salts exported in the form of preparations coming within the provisions of the Dangerous Drugs Act.

The value of the exports cannot be stated exactly, but from information supplied by the manufacturers it is considered that the average prices ruling in 1920 and 1921 may be taken at about 17–18 shillings for morphine and 14–15 shillings for morphine salts in 1920, and 12–14 shillings for morphine and 10–12 shillings for morphine salts in 1921.

A Lecture

ON THE TREATMENT OF EPITHELIAL TUMOURS OF THE URINARY BLADDER,

BASED ON A CONSIDERATION OF 162 CASES PERSONALLY OBSERVED AND TREATED.

Delivered at the Mayo Clinic, Rochester, Minnesota, U.S.A.,

By FRANK KIDD, M.A., M.CH. CAMB.,
F.R.C.S. ENG.,

LATE SURGEON TO THE LONDON HOSPITAL, ENGLAND; MEMBER OF THE INTERNATIONAL SOCIETY OF UROLOGY; MEMBRE DE L'ASSOCIATION FRANÇAISE D'UROLOGIE.

FIRST it must be my pleasant task to thank Dr. William J. Mayo, Dr. Charles E. Barnett, and the Mississippi Valley Medical Association for the honour they have done me in asking me to address so distinguished a body of American surgeons. I feel very deeply moved by the warm reception accorded to me here. The Mayo Clinic is the Mecca of the surgical world. Just as the Mahomedan attained merit by making a pilgrimage to Mecca, so the surgeon, in whatever country he works, looks forward to the time when it is his privilege to visit this shrine of modern surgery raised by the genius of the brothers Mayo. When he has made the pilgrimage he can never be quite the same again. He will return to his work at home with his outlook widened and his standard of work ever set by this amazing organisation of genius. Working as I do in a land of individualists, but with my eyes ever turned to the advantages of organisation and team-work, I can only say that to visit this shrine is to me an inspiration and will be, I hope, a never-to-be-forgotten memory. It is difficult for you to realise with what feelings, not only of admiration but also of affection, we surgeons of other countries are possessed when we gaze upon Rochester, which calls to our minds a vision of what the future of medicine may yet bring to suffering humanity.

Speaking as I am to a gathering of distinguished practising surgeons I feel very humble in presuming to bring before them to-day the fruit of work based on such a moderate number of cases. Nevertheless I realise that before experts the chief value of any man's remarks can but reside in an attempt to state and evaluate his actual results in practice.

DIFFICULTIES OF THE PROBLEMS.

Modern surgery demands more and more a knowledge of end-results. How can it otherwise justify the surgical attacks made upon disease, save by showing that thereby at least some valuable lives are saved and others rendered more comfortable and more prolonged? I will therefore endeavour to confine my remarks as much as possible to what I have found practicable in attacking the problem of bladder cancer. I can only plead for my results first that the problem is one of intense difficulty because far less than half the cases are sent up at a time when surgical attack with a prospect of cure or relief is possible; secondly, that I have only been working at the problem practically for a brief ten years, some years having been cut out of my working life by the European war, when war surgery took precedence over civil surgery; thirdly, that it has been my lot to work under the English individualistic system, as a general surgeon in a large general hospital, to whom has fallen only his ordinary share of bladder cancer cases; fourthly, I have had to work at the problem whenever opportunity offered in a busy life devoted to dealing with a great variety of other general and special surgical problems.

The problem of bladder cancer has appealed to me ever since 1903, when it was first my privilege to work under the stimulating auspices of Hurry Fenwick, my revered master and teacher. Into his wards I saw coming in considerable numbers those pathetic sufferers from bladder cancer, some with late cancer, with excruciating pains and terrible strangury, some with recurrent papillomata, their faces pale as paper and their tissues completely exsanguinated. Hurry Fenwick wrestled with the problem by means of open operation carried out from within the bladder for papillomata, and with partial and total cystectomy for true cancer. Yet I felt that the technique held room for improvement. Too often the cases of papillomata recurred and returned again and again for operation. I reflected that, after all, many cases of malignant papilloma and some cases of papillomatous carcinoma were for a definite period confined to the bladder wall itself, and that the spread to the tissues around and to the lymphatic glands was usually slow. Here was room for success if a more radical type of operation could be devised. The cause of death was not so much spread to distant parts as local accident—such as loss of blood, pain, and cystitis, followed by dilated ureters, pyelitis, and uræmia. Could one but get the cases early, and devise a more radical type of operation, an increasing amount of success and some lasting cures might be expected.

PROVISIONAL CONCLUSIONS.

I considered an attempt to work out the spread of bladder cancer along the lines of Sampson Handley's work on cancer of the breast, but I found that this was impossible as so few cases of bladder cancer ever came to the post-mortem room at the hospital; they died at home or in the infirmaries. Such a research awaits the earnest worker and would bear rich fruit. I had therefore to use what opportunities operations afforded for noting the spread of bladder cancer. My provisional conclusions are that malignant papillomata and even some papilliferous carcinomata of the bladder break through the muscular coat of the bladder fairly late. At first the muscular coat forms a barrier to the malignant cells, so that they tend to spread in the submucous coat of the bladder and give rise to small daughter warts in their neighbourhood. They also spread by local contact and implant their offspring on opposing sides of the bladder. Even when they break through the muscular coat the progress of the majority, which tend to lie just above the ureters, is barred for some time by overgrowth of dense fibro-fatty tissue in the connective tissues that surround the base and sides of the bladder, accompanied by considerable overgrowth of the veins in this tissue. Less often these growths lie on the trigone and so may burst into the rectum; or high up on the superior and lateral walls when they break into the peritoneum and give rise to perforation and peritonitis or intestinal obstruction from adhesions or even multiple growths in peritoneum and liver. These growths are the exception; the majority invade the pelvic cellular tissue that houses the lymphatics which run up along the sides and back of the pelvis, first to a gland that lies on the side of the external iliac vein at the middle of the pelvic brim, secondly to a group of glands which lies just beneath the bifurcation of the aorta. From these two sets of glands the cancer cells may eventually spread to the lumbar chain on each side, but this appears to be a late event except in rapidly growing excavating carcinoma of the bladder. Bony metastasis is an uncommon event.

I concluded that in some forms of malignant disease of the bladder, especially the common papillomatous type in the region of one ureter, the lymphatic spread of cancer cells was slow and long delayed by nature's defensive forces. That the common causes of death were not so much invasion of distant parts as the result of local accidents of position such as dilated ureters and uræmia, infection cystitis and pyelitis, exhaustion from loss of blood, spread to rectum and peritoneum. Get the cases early enough and diathermy or a well-designed operation might hope to remove all the local growth, and this is what I have found. It is true I have not been able to get as many as half my cases, perhaps not a third, sent up at a stage where radical treatment has been possible. This is partly the fault of the patient who neglects his symptoms, but I am afraid it is sometimes the fault of the medical adviser, when he fails to realise that when faced with a case of painless hæmaturia, *the only effective course to pursue is to insist on immediate cystoscopy*. The emergency is just as important and urgent as those of bleeding from the womb or even of acute appendicitis, yet many men will not realise this. The lure of drugs still appeals; they order medicine, nature stops the bleeding. The doctor praises his medicine and the patient believes him until the bleeding has returned again and again; doctor and patient become alarmed, the patient is sent up for cystoscopy, and they are then surprised to find it is too late for effective treatment. This paper will have been written in vain if I cannot persuade an increasing number of medical men that the outlook and prospects of cure for bladder cancer have immensely improved. Epithelial tumours of the bladder can be cured, but only, in a large number of cases, if the practitioner insists on immediate cystoscopy.

Bladder Habit.—I have also come to the conclusion, based on experience, but incapable, I suppose, of absolute proof, that some bladders become the victim of a vicious habit or tendency to develop papillomata which is inherent in the whole epithelial membrane. In several patients I have destroyed by diathermy one or more early bladder tumours of papillomatous or ulcerative type and they have remained perfectly well for some years; yet they have eventually returned again with early fresh tumours in quite different parts of the bladder. I believe these represent not recurrences but entirely fresh tumours.

EDWIN BEER'S DIATHERMY TREATMENT.

In casting about for a suitable type of operation I came to the conclusion that the old method of opening the bladder on its anterior wall and snipping away the growths was not radical enough. I felt that the bladder must be shelled out before opening it and its blood-supply controlled so that one could cut out in one piece from the outside the invaded cellular tissues and large pieces of the bladder wall and so hope to get wide of the growth. I was feeling my way along these lines in the years 1911 to 1914 when I read two papers which took me a long way on the road. The first was by Nicolich, of Trieste, the reference to which I cannot now trace, who published experimental work on dogs, whereby he showed that the whole of the bladder except the trigone could be removed from dogs and yet the bladder would very quickly re-grow and form a fresh and active organ. The second was a paper by Bentley Squier, of New York (1914), to whom I cannot sufficiently acknowledge my indebtedness. I was feeling my way along his lines when his paper appeared, but it showed me how to step boldly forward. This is how the problem shaped itself for me as regards partial cystectomy. Meantime another star had arisen above the urinary horizon when Edwin Beer, of New York, published his epoch-making papers on diathermy or fulguration for papillomata of the bladder in 1910 and 1911. It was given to Beer to make light of theoretical objections and to prove by practical demonstration that papillomata could be effectively destroyed by high-frequency currents applied through the operating cystoscope. Beer's work has revolutionised the treatment of papillomatous bladder tumours. I am ashamed to say that I did not appreciate what had happened until the autumn of 1913, when I obtained a suitable high-frequency machine and was able to begin work on my first cases in January, 1914. In 1914 I was able to publish one of the first papers on this subject in England.

DIAGNOSIS.

The problem has thus become one calling for exquisite niceness of judgment in the diagnosis of bladder tumours. There are some cases where we can say at once, "This is a simple papilloma and will react to high frequency." It melts away under that treatment and the patient is saved from a terrible, long-drawn-out and fatal malady, and incidentally from a major operation with its definite risk to life—a point some doctors still fail to appreciate, as I shall point out later in this paper. There are others where we can say, "I am not certain, we must try the effects of diathermy." In some it is successful, in others it does no good, and these we then submit to subtotal cystectomy. In others we can say at once, "This is not a case suitable for diathermy" and we can proceed at once to subtotal cystectomy. Then there come a few exceptional cases where total cystectomy, and diversion of ureters may be attempted, but as we get the cases earlier diathermy, subtotal cystectomy, and perhaps radium will more and more oust the need for the operation of total cystectomy which is bound to remain a comparatively rare operation. Many of my cases of subtotal cystectomy were to all intents and purposes cases of total cystectomy, as in many of them more than three-quarters and even as much as seven-eighths of the bladder were removed. Finally, there come those quite inoperable cases which are often left alone or else submitted to permanent drainage. These are some of the saddest cases in surgery. More than half my cases arrived too late. It is in this type of case that radium, deep Rontgen ray therapy, and open diathermy may be used in the hope of palliation, and in the expectation of producing arrest of growth in some cases.

Painless hæmaturia is a danger signal, demanding cystoscopy at the earliest possible moment. Seventy out of every hundred cases of painless hæmaturia are suffering from a tumour of the bladder or kidney. These statements might be framed and hung up like the old-fashioned texts in every surgery throughout the land. Occasionally two other symptoms are met with—"pulled ureter," or pain in one kidney produced by pulling of the tumour on the ureter or by blocking thereof, and "corked urethra," or intermittent interruption of the stream of urine, the tumour getting caught in the entrance of the deep urethra. One patient treated by me by means of cysto-diathermy went for three years without trouble. Then he told me he noticed a peculiar feeling in his bladder which he could not describe but which he had noticed before previous to his first attack of hæmaturia. Like a wise man he came up at once for cystoscopy though he had noticed no bleeding. There at once could be seen a tiny fresh papilliferous carcinoma which I was able to destroy with one diathermy treatment, and he has since remained perfectly well.

The proportion of males to females in this series is 127 to 30. As regards the duration of symptoms, one patient had bled for more than ten years before being sent up for cystoscopy, yet I was able to cure him permanently by one diathermy treatment. One patient, a doctor's wife, had bled for six years before she was sent up. Partial cystectomy cured her. One patient, a doctor, started bleeding at the age of 15. He had three or four operations at intervals up to the age of 35. He came up to me at the age of 45, having been bleeding on and off for 30 years. He had continued his practice in spite of terrible agony until the day before he came up. I transfused him with blood, hoping to improve his condition sufficiently for operation, but he died of uræmia within the week before anything more could be done.

RESULTS OF DIATHERMY OPERATIONS.

I will now proceed to the most important part of my paper—namely, the actual results I have been able to obtain in cases of epithelial bladder tumours. I can only regret that the results are not better than they actually were. Out of 80 patients who came up early enough for diathermy or partial cystectomy, 41 or more than half are known to be alive and well—one 11 years, and many as long as seven and eight years, later; and it is probable that 55 are alive and well, though I cannot trace them to 1922. I believe that even these figures will surprise many who are apt to think that bladder tumours are incurable. As a result of this ten years' experience I feel I have learned enough to justify a hope that the next ten years' results will be considerably better, provided I can obtain the cases at the earliest possible moment—namely, during the first attack of hæmaturia.

Case Groups.

Group.	Cases.
1. Simple papillomata or small recurrences noted after operation treated by diathermy through the cystoscope	28
2. Inflammatory papillomata treated by diathermy	2
3. Malignant papillomata treated by diathermy through the cystoscope	26
4. Partial or subtotal cystectomy	28
5. Cystotomy with local removal from inside the bladder	17
6. Total cystectomy	5
7. Ureterostomy	6
8. Permanent drainage	18
9. Where surgical treatment was not advised or refused	24*
10. Radium treatment	5
11. In which wrong diagnosis was made	2
12. True papillomata of the male urethra treated by diathermy	1
Total	162

* Plus a number seen as out-patients and not recorded.

GROUP 1.—SIMPLE PRIMARY OR SMALL RECURRENT PAPILLOMATA.

This group contained 28 cases of primary simple papillomata of the bladder or of small single papilloma recurring after operation treated by diathermy applied through the cystoscope. As regards the differential diagnosis between a simple and malignant papilloma, in the first place I wish to state that I do not approve of taking portions of bladder growths away with an operating cystoscope for purposes of microscopic study. The risk and inconveniences involved in such a course seem to me to outweigh any possible advantage to be gained by the patient. The snipping-off of portions of living tumour inside the bladder is bound to result, in a number of cases, in the implantation of fresh tumours on other portions of the bladder wall. Again, when a surface portion of such a tumour is submitted to microscopical investigation I doubt if it is possible for anyone to give an accurate opinion as to the question of malignancy. Even when a histological report comes in after I have removed a bladder growth widely by open operation I find that the pathologist's report sometimes differs widely from the actual character of the tumour as manifested clinically. Nothing can be more surprising or call for so much food for thought as when we have opened a bladder and removed a portion of its wall containing what clinically is obviously a malignant tumour, than to receive a pathological report stating that microscopically the tumour is benign and not malignant. It makes one doubtful of the power of the microscope in distinguishing between these two classes of tumours. I am aware that Buerger has published (1916) a brilliant paper stating the minute differences whereby such a histological differentiation can be made. Nevertheless, my own experience does not lead me to trust such findings, and that being so I do not care to subject my patient to the risks of tumour implantation from disturbance of the living tumour in the bladder. One has to make a judgment as to the question of malignancy or benignancy on clinical grounds if one wishes to attain the best results. Especial attention is directed to the length of the history and a comparison of that with the size and appearance of the tumour, the delicacy and length of the fimbriæ and the pedicle, the appearance of the bladder in the region of the pedicle, the question of singleness or multiplicity, the feel of the base of the bladder per rectum or per vaginam, and finally in some cases by the reaction of the tumour to diathermy. Some tumours that look malignant react at once to diathermy, and others that look innocent prove refractory, eventually needing open operation; the latter are always malignant. The age of the patient is of relatively small importance. Some most malignant papillomata occur in the young and some quite benign in the aged. I believe that the best judgment can be made by an experienced cystoscopist, but even here many errors are bound to creep in and the problem must remain most difficult. Of the 28 cases that appeared to me to be clinically simple and including two or three cases of tiny recurrences appearing some years after an open operation, the average age was 43 years. The average number of diathermy treatments was rather less than three, and of these all appeared to be completely destroyed within a few months of the treatments.

As regards the late results, 21 cases have been traced up to 1922, and of these 19 cases show no signs of any recurrence—1 nine years, 3 eight years, 1 seven years, 5 six years, 4 five years, and 1 four years since treatment. It appears, then, that treatment by diathermy is far more permanent and less likely to give rise to recurrences than the old-fashioned open operation. This is because the tumour is cooked or coagulated and destroyed from the top to its very roots. There is, then, little chance of implanting seeds of fresh tumours during treatment as happened in the old operation, when so often within a year multiple seedlings appeared in the abdominal incision on the bladder side, a picture with which we must all be familiar. Two of these 21 cases relapsed, 1 six years and 1 two years later, and have since been submitted to open operation and are alive and well up to 1922. The remaining seven cases were followed up for a year or more, remaining quite free from recurrence, and it is justifiable to assume that they were cured. The results, then, are 19 known and 26 probable cures out of 28 cases treated by diathermy alone. The age of these patients was considerably higher than is usually considered common for cases of simple papillomata; the oldest was a man of 71 who has remained free and well for five years since his treatment, and the youngest 21. As is usual, the predominance of males over females is large—24 to 4—which makes the treatment all the more difficult. Another point worthy of note is the extraordinarily long time some of these patients had been allowed to bleed before they were referred for diagnosis. For instance, one man had bled on and off for ten years, yet when I saw him I was able to destroy a very large and long-pedicled papilloma at one sitting, and he has remained cured for eight years. The bright side of the picture appears in the case of a woman referred to me only eight days after her first hæmaturia; there I found a tiny little carcinomatous ulcer, the smallest I have ever seen, and destroyed it under an anæsthetic at one sitting of diathermy.

It may be asked whether there are any risks attaching to the treatment. There are, but they should be almost negligible in the hands of an expert. There was no fatality in the whole group of 54 cases treated by diathermy. There were two cases only where serious hæmorrhage followed a vigorous treatment. In one there was clot retention, which I remedied by means of a lithotrite and Bigelow's evacuator, with rest in bed for a few days. In the other, occurring at the hospital during the night after my treatment in the afternoon, and suffering from clot retention, the surgeon on duty opened the bladder and let out the clot, a quite unnecessary interference. If a papilloma is seen to be lying high up on the superior wall of the bladder against its peritoneal surface care should undoubtedly be exercised not to carry out too severe a treatment when the pedicle has been bared and exposed. In such cases an additional safeguard is to carry out treatment without any anæsthetic, so that the patient's feelings can be used as a guide to the severity of the burning or electro-coagulation.

I have only once seen cystitis arise after a treatment; it was undoubtedly set up by spontaneous infection of the sloughs as they came away after the treatment. This is because I am meticulously careful in the sterilisation of my equipment and always use a strong and efficient antiseptic (1/4000 oxycyanide of mercury) for filling the bladder. That is to say, I have carried out between 150 and 200 treatments in 54 cases and have only once seen cystitis follow. Otherwise the urine has remained perfectly clear, and if it was purulent when I first saw the case it has quickly become clear as a result of the treatments. Praetorius states that instillations of 20 per cent. colloid silver at intervals of three days between the treatments hastens the separation of sloughs, and I intend to try this in future. Hexamethylene-tetramine is exhibited throughout the course.

When I first started I was inclined to carry out diathermy treatment without an anæsthetic, owing to administrative difficulties at the hospital and to the shortness of beds. Using my new machine I am nowadays inclined to give an anæsthetic anyhow at the first sitting. Using an anæsthetic I am able with my new machine to destroy completely the top of the tumour at one sitting. I can then wash away the debris and having re-filled the bladder with a clear medium I can proceed at once to give a strong treatment to the actual pedicle. In this way fewer treatments are required and the cure is quicker. Spinal anæsthesia is the ideal as far as a non-irritable bladder is concerned, but it means that the patients need to stay several days in bed afterwards; otherwise they tend to develop a bad headache. For this reason I usually employ open ether and oxygen, so that they can go home the next evening. I find by experience that an interval of at least three weeks and not more than four weeks is the best to allow between the treatments. This gives time for all sloughs to separate and yet not enough time for fresh growth to occur, and it gives the urethra time to settle down. I am aware that this is in contradistinction to the advice of Edwin Beer, who states that he carries out the treatment every seven days. After apparent cure the patient should be urged to report at least once a year for cystoscopy. A tiny early recurrence too small to give way to hæmaturia can be destroyed with ease at one sitting. At one time I tried to combine the old-fashioned snare with diathermy. I had made an insulated snare which I could attach to my diathermy machines. With this I snared the pedicle and turned on the current. The effect was to destroy the pedicle, but the top of the tumour came away in a lot of broken living pieces and there seemed to be a risk of implantation from these pieces so I gave the method up.

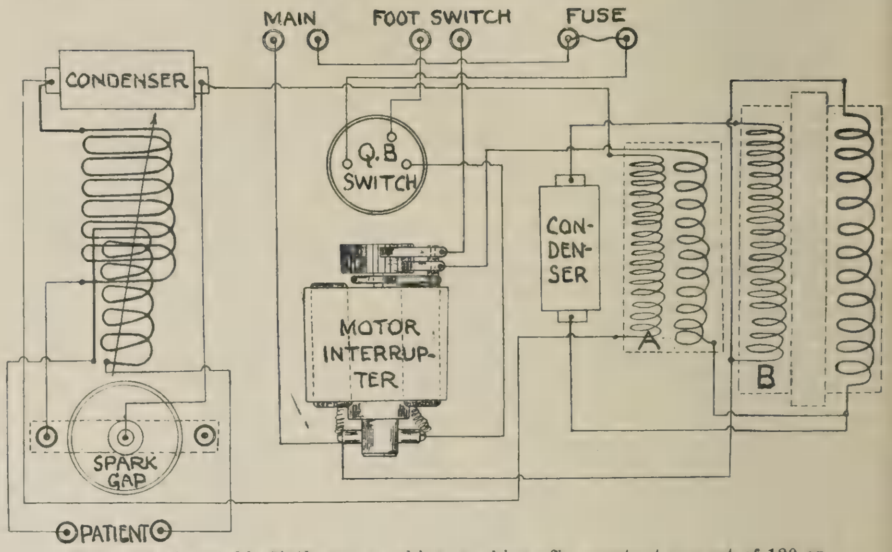

Diagram of portable diathermy machine, working off a constant current of 120 or 240 volts, and weighing 34 lb.

Group 2.—Inflammatory Papilloma.

In this connexion I wish to bring forward two cases of inflammatory papilloma treated by the diathermy current (Cases 116 and 117). In certain patients with chronic cystitis and pyelitis due to the colon bacillus I have observed isolated buttons of hyperplastic inflammatory tissue covered with hyperplastic epithelium closely simulating epithelial tumours. These buttons are sessile and lie around the ureters and on the trigone. They are flattened or sessile and covered with corrugated epithelial tissue not so exuberant or so fimbriated as the epithelial tentacles of a papilloma. I have seen a similar papilloma when doing a post-mortem examination on a case of tuberculosis of the bladder, but so far have not encountered one in the living subject. The existence of such inflammatory nodules should not be forgotten when considering the diagnosis.

Case 1.—Female, aged 25 in 1917. Acute appendicitis accompanied by acute pyelitis due to the colon bacillus. Appendix removed. The pyelitis became chronic and needed renal lavage for its cure. Very marked strangury, caused by the presence of a number of inflammatory papillomatous buttons scattered over the trigone. I treated them on several occasions with the diathermy current until they had completely disappeared and the symptoms were relieved.

Case 2.—Female, aged 40 in 1919. Long-continued strangury, *B. coli*, streptococci and pus in the urine. Cystoscopy, two large inflammatory papillomatous-like buttons on the upper part of the trigone towards the right ureter, one sessile, the other having a distinct pedicle. These buttons were treated three times with diathermy and the kidneys washed out, with complete relief of the symptoms and a return of the appearance of the trigone to the normal.

I have lately discovered that Ewing refers to this subject in "Neoplastic Diseases" (W. B. Saunders Company, 1919).

"The multiple villous tumours must be distinguished from a form of diffuse low papillary inflammatory hypertrophy of epithelium, which has been known to cover almost the entire mucosa, producing a velvety surface. This condition is a curious exhibition of the regeneration tendencies of the irritated mucosa, is seen in exstrophy of the bladder, with calculus, and about other tumours, and may be arrested by curettage (Keyes, Fenwick)."

Until 1920 I was content to use the machine devised by Lowenstein of Berlin, called the "urodiatherm." I found that it was continually getting out of order owing to overheating of the spark gap, so that prolonged treatment could not be carried out at one sitting, and also no very profound effect could be exerted on the deeper tissues as the quantity of current passing was not great enough. Mr. Schranz, of the Genito-Urinary Manufacturing Company, 66, Margaret-street, London, at my suggestion worked out the design of a fresh machine. Making use of the Wilson interrupter coil (as devised for use during the war for naval wireless, and described in detail on pp. 52 and 53 of Fleming's text-book on Wireless Telegraphy) he has designed me a machine which gives excellent results. It works off a constant current of either 120 or 240 volts, and gives a minute gradation of current from 0 up to one ampère. The spark gap is of remarkable consistency and can be used continuously for 15 minutes at a time without overheating. With this machine it is possible to start each application of current at a very low ampèrage and gradually increase it up to a maximum. In this way one obtains a maximum of true "diathermy" heating and consequent coagulation of the deeper parts of the tumour without producing charring and gassing on the surface of the tumour, a most important point emphasised by E. P. Cumberbatch.[1] The machine only weighs 34 lb., is portable, not easily knocked out by a jar, and appears to me to be simple and efficacious. Its only defect is that it cannot so far be designed to work off an alternating current without becoming too bulky to be portable. Using this machine (see diagram) I have been able to destroy very large clinically malignant papillomata at one sitting.

---

[1] Diathermy: Its Production and Uses in Medicine and Surgery, 1921. London: Wm. Heinemann, Ltd. Reviewed in The Lancet, 1921, i., 1306.

DESCRIPTION OF MACHINE.

At "make" the brushes on the motor interrupter are connected. A current rises in the inductance (B) and stores energy in its magnetic field. The condenser (C) is charged to the potential of the supply, the charging current passing through the primary windings of the spark coil (A). At "break" the brushes sever contact; the energy stored in the choking coil and condenser is now isolated. The condenser immediately discharges its energy into the choking coil and is again charged in the reverse direction by the falling magnetic field of the choking coil. At that moment the choking coil is short-circuited and the condenser discharges with greater speed through the primary of the spark coil. The energy at the terminals of the secondary is then transformed into a high-frequency current by the usual oscillatory transformer, spark gap, and condenser. The size of the case is 19 by 8 by 11¼ in., its weight 34 lb.

I feel that the profound and important distinction is not always recognised between fulguration or sparking, a process which produced superficial destruction by charring of a growth and diathermy, which produced coagulation and necrosis of the malignant cells in the pedicle and deeper portions of a tumour. This effect is obtained by heating up the deeper portions by means of the concentration in those portions of a high-frequency current sufficient to insure necrosis of the cells without giving rise to charring. If too strong a bipolar high-frequency current is turned on directly the electrode is applied to the tumour, charring takes place on the surface, the electrical resistance of the charred mass rises to a high degree, and in consequence the heating effect of the current on the deeper portions is cut off and rendered ineffective. Yet it is the deep heating effect that we ought to aim at if we wish to get quick and lasting results. We only require a moderate yet sufficient rise of temperature to produce necrosis of the tumour cells, a temperature which is well below that needed to produce charring and gassing. This effect can be attained only if we turn on a very low current at the start and work it up gradually over a period of 20 or 30 seconds until a faint whitening begins to appear in the region of the electrode. Then is the time to turn off the current. Do not remove the electrode from the tumour until the current has been turned off. Otherwise sparking and charring occur, and the electrode tends to stick to the tumour and when pulled away causes bleeding. It is to the strict observance of these points that I attribute my success in obtaining quick and lasting results—points which are clearly brought out in Cumberbatch's book. The aim is to apply a deep diathermy effect and not mere superficial fulguration.

(To be continued.)

JENNY LIND HOSPITAL FOR CHILDREN, NORWICH. The annual report of this institution states that the number of in-patients admitted during 1922 was 901. The daily average number of beds occupied was 44·3, the number of operations in hospital 339, dressings and casualties in the receiving room 612. In the out-patient department the number of new patients was 2456, the number of attendances 10,513, and 175 operations were performed. The percentage of cases stated to be "cured" (68·7) was considered gratifying; 12 per cent. were marked "relieved"; 8·76 per cent. were discharged for special reasons; the death-rate was 5·88 per cent.; and 4·66 per cent. remained in hospital at the end of the year. The ordinary income for the year was £6227, almost the same as that of 1921—viz., £6254—and the total expenditure amounted to £6782. The average daily cost per patient was 8*s*. 4*d*; the committee are satisfied that the greatest economy is exercised. It has been decided to appoint an honorary ophthalmic surgeon and a male house surgeon.

The Milroy Lectures

[ABRIDGED]

ON

CANNED FOODS IN RELATION TO HEALTH.

Delivered before the Royal College of Physicians of London on Feb. 22nd, 27th, and March 1st respectively

BY WILLIAM G. SAVAGE, M.D., B.Sc. LOND.,
MEDICAL OFFICER OF HEALTH FOR THE COUNTY OF SOMERSET.

I.—THE IMPORTATION AND CONTROL OF CANNED FOODS.

WHILE available literature has been utilised, the lectures are mainly based upon four years' systematic laboratory investigation by myself and colleagues, together with many special inquiries and studies of methods in this country and in America, the work being done for the Food Investigation Board.

The introduction of the art of canning is due in large part to the stimulus of war, and, indeed, originated in the bounty of 12,000 francs offered by the French Government during the Napoleonic wars for an improved method of preserving foods. This was awarded in 1810, and commercial canning dates from 1820. The gradual development of the industry was accompanied by general improvement in methods of canning, more suitable types of tins, wide and continuous extension of the kinds of foods canned, and a more scientific understanding of the processes involved.

The importations of canned foods which are retained in Great Britain amounted in the year 1921 to over 248,000 tons, or about 278,000,000 separate tins of 2 lb., this being taken as the content of an average tin. This enormous quantity was composed of meat 22,500 tons, fish and other marine products 32,700 tons, fruit and vegetables 88,300 tons, and condensed milk 105,000 tons. In addition a considerable quantity is manufactured and consumed in this country. Most countries came under contribution, but most meat (41 per cent.) came from South America, with Australia second (30 per cent.). Japan headed the list for salmon, with U.S.A. a close second, while condensed milk and fruit were mainly from U.S.A.

The supervision exercised over canned foods comprises supervision at the source and in process of manufacture, that exercised by the trade, the control exercised at the ports of entry, and supervision after distribution. Supervision at the source was discussed mainly in relation to U.S.A. and Canada, and is complicated because of the double series of laws—those enforced by the Federal Government, and those by the individual States. Apart from meat the procedures are very similar to those in this country, but under the Meat Inspection Act of 1906, and supplementary legislation, a very comprehensive system of control is exercised. This involves veterinary and lay inspection of all carcasses, and some 2500 employees are continually engaged in this work. All animals which are satisfactory are stamped with the Federal inspector's stamp.

The control exercised at the ports of entry in this country is derived from powers in the Unsound Food Regulations, 1908. Under Article IV., if the canned food consignment is suspect in any way a notice of detention is served so that a detailed examination may be made. Article VIII. gives powers of sampling and facilities for the detailed examination of selected samples.

Another source of information which is valuable is the results of examinations of canned goods made by and for the trade. These examinations are utilised to a considerable extent, as with the present staffing it is not possible for officers of the local authorities themselves to examine more than a small percentage of the tins which come into the area of their authority.

The reliability of the methods of detecting unsoundness from an examination of the unopened tins demands critical consideration. 431 samples of different canned foods were submitted to detailed bacteriological examination after the opinions of the food inspectors had been elicited. The results showed that in all, judgment was correct in 73 per cent. of the samples, but that this varied greatly, and for meat, which included many doubtful tins, was as low as 41 per cent. For the tins which were springy or showed an abnormal shake sound the percentage of error was very high, and many tins with sound contents were rejected.

The conditions as regards labelling are unsatisfactory. Much canned food reaches this country unlabelled, and is then given a fancy label which may be used for the same type of food but from very different sources, while the same consignment may be labelled with several different labels. This makes it impossible to trace a consignment should, for example, a food poisoning outbreak occur. A system of identification stamping is desirable.

The lecturer went on to discuss the thorny subject of dating canned goods, strongly expressing the opinion that the date of preparation should be stamped on all tins. He dealt with the loss of canned foods by the contents becoming unsound. This loss falls into groups factory loss and post-factory rejections. For the former anything over 0·5 per cent. would be considered unwarranted and demanding strict investigation. Post-factory wastage may be very considerable. Rejections from four areas in London in 1920 amounted to 1,364,272 lb. from canned meat alone, a loss of over £68,000.

The methods of destruction of these foods is not completely satisfactory, as although much is destroyed and the rest released under definite restrictions for animal food, manure, or fat extraction, the methods of supervision are not always adequately controlled, and there is a possibility that some of the best of it may be picked over and come back into circulation. A common practice is to pierce the tins before they leave the supervision of the local authority, but this is not a universal practice.

II.—Spoilage of Canned Foods.

The prevailing view is that canned foods remain sound because the food is rendered sterile by the application of heat and is maintained sterile by being kept in hermetically-sealed containers. This simple conception does not represent the facts. Of 178 sound samples purchased in shops, 38·8 per cent. were not sterile, excluding sweetened condensed milk which is never bacteria-free. The percentage not sterile varied from 100 for crab, 83 lobster, 64 meat to 22 for fruit. More important than absolute sterility is the types of bacteria present. These include yeasts, obligate anaerobes, sporing aerobic bacilli, thermophilic bacteria, and micrococci. The two important points in determining the potential ability of an organism to cause unsoundness in canned foods are its proteolytic and its fermentative properties. The former was judged by its ability to liquefy blood serum and digest milk, the latter by carbohydrate fermentation. Organisms such as *B. proteus* or the obligate anaerobes which usually possess both groups of properties will be the most potent causes of decomposition. Organisms which are fermentative but not proteolytic, such as the *B. coli* group, will cause tins to become "blown," but may cause surprisingly little change in the contents. Those, such as the micrococci, which usually exhibit neither property are comparatively harmless.

Each group of organisms has, however, to a certain extent to be considered in relation to the kind of food. Yeasts are potent causes of decomposition of sweetened condensed milk, to a lessened extent for unsweetened milk and fruit, and are of little or no importance as a cause of spoilage for meat and marine products. Micrococci cause some spoilage in unsweetened milk, and probably some types are of importance for fruit but otherwise cannot initiate spoilage. Anaerobic sporing bacilli can decompose any kind of food. Sporing aerobic bacilli, such as *B. subtilis*, *B. mesentericus*, are so widely distributed in all types of canned foods and in sound and unsound tins that the possibility of their acting as decomposing agents is of very great importance. They are not fermentative, but the majority are proteolytic. Detailed study shows that they are often present in the spore form in all types of canned foods, and while they usually remain dormant under certain conditions they can decompose the contents. These conditions are of great practical importance. In a striking experiment it was shown that when 17 perfectly sound shop-purchased tins of different marine products were punctured and given sterile air access, incubated for 5–16 days, and then sealed up and re-incubated, no less than 12 became quite unfit. Sporing aerobic bacilli were found in 16 (i.e., all but one), anaerobes in 9, and other organisms in 9. Four control tins, but not punctured, remained sound and sterile on examination. This and a long series of other experiments shows that very many of these sound tins contain bacilli even of decomposing type, which remain dormant until lit up to activity by air access, and that this applies even to the anaerobes. Another series of experiments demonstrated the same thing for the yeasts and showed that a few yeasts even of fermenting type may be present in sound tins of sweetened condensed milk (in 43 per cent. in one series) and cause no decomposition so long as the supply of oxygen is restricted. Once, however, they have produced sufficient enzymes gaseous fermentation will be largely independent of the oxygen supply. A new and hitherto unrecognised type of decomposing bacillus, *B. pleofructi*, as a cause of spoilage of fruit, was isolated and found to be of great practical importance.

The investigations emphasise that air access is an extremely important factor in spoilage, not because it allows bacteria to get in but because it permits of the multiplication of bacteria already there. Keeping down the initial number in the food before the tin is closed is also of much importance. The problem of "processing"—i.e., the so-called sterilisation after the tin is closed—is of great complexity, and not merely a question of a definite temperature for a given time. The destruction of the bacteria is materially affected by the physical properties of the food, the hydrogen-ion concentration, the size of the tins, the initial temperature, the subsequent cooling, and other factors. The changes which take place in foods after canning are of considerable interest. In some foods they are slight, but are considerable for milk and fish. In milk, particularly sweetened kinds, they take the form of marked thickening and darkening in colour. The changes are of considerable practical importance. The lecturer discussed these in some detail and also the considerable changes which take place in stored fish.

The possible danger to health from the consumption of canned foods which show signs of decomposition is an important question because there is a real danger that incipiently decomposed food may be canned and all living bacteria killed by subsequent sterilisation. Such food will not decompose further in the can and the tin will not show any signs of unsoundness. In spite of prolonged investigation no satisfactory methods could be devised for reliably detecting whether such slightly decomposed food had been used. Certain chemical determinations are, however, of value and are capable of improvement. Fortunately there is no evidence that the consumption of such tainted food is liable to set up disease or illness. There is no evidence of the presence of bodies poisonous by feeding, while a long series of experiments with kittens fed repeatedly upon both slightly and very putrefactive canned and other meat failed to demonstrate any definite signs of toxicity. No danger to health from this source is to be apprehended provided the specific organisms of food poisoning are absent.

III.—CANNED FOODS IN DIRECT RELATION TO HEALTH.

Scientifically considered any possible menace to health from the use of canned foods may be bacterial, animal parasitic, chemical, or nutritional. As a vehicle for the conveyance of animal parasites they have no special significance, but the others require detailed consideration. The bacterial sources of infection are mainly specific food poisoning from the Salmonella group, botulism and the possibilities of food poisoning from the use of putrefactive food not specifically contaminated. Salmonella food poisoning is of great importance in connexion with canned foods, and I have collected particulars of 51 such outbreaks, all in Great Britain. It is certain that very many of them are never reported or known officially. The infected canned foods do not differ in appearance, odour, or taste from sound foods, nor are there any changes in the containers. They form two groups. In the one living members of the Salmonella group are present; in the other the heating given to the tins in manufacture has killed the living bacilli and left the heat-resisting toxin. Of 43 outbreaks of the series in which this could be ascertained 16 were due to living bacilli and 27 to undestroyed toxins, without living bacilli.

The influence of season is distinctly less noticeable for canned-food outbreaks than those where the vehicle is fresh food. They show only a moderately increased prevalence in the warmer months. In my series the canned-food vehicle percentages were, respectively, meat 51, fruit 10, salmon 31, other marine foods 8. In all, or practically all, these outbreaks the food was infected before the tin was sealed up. The prevention of outbreaks from this cause is, therefore, a matter of exposure of the tins to a temperature adequate to kill toxins as well as bacilli, and in part to prevention of infection of the food at the source. Since the outside of the tins and the contents show no deviations from the normal ordinary methods of inspection of the tins are powerless to assist.

In this country food poisoning from the Salmonella group is far more important than botulism. The latter has, however, a special relationship to canned foods, and the risk from this source demands detailed consideration. Outbreaks of botulism mostly occur in America, and through the kindness of Dr. Meyer, of California, who has done so much in this subject, I have particulars of 84 outbreaks in U.S.A. and Canada, all from canned or bottled foods. They comprise 319 cases with 206 deaths, a case-mortality of 64·6 per cent. Of these 52 were home and 31 commercially canned foods, 1 being doubtful. The primary seat of *B. botulinus* is the soil. It has been found widely distributed in the soil of California and more prevalent in virgin than in cultivated soil (57 to 27 per cent.). This is an important point, and suggests that animal excreta is not a vehicle, nor is the intestinal canal the natural home. Dr. Meyer found the organism in 5 (and 2 others doubtful) out of 64 samples of soil from different parts of England which I sent to him in 1921. The spores have been isolated from fruit and vegetables in California.

The Loch Maree outbreak is the only outbreak of botulism which has ever occurred in England, so far as I can trace, but the possibility of its introduction from canned fruit or vegetables demands very careful and detailed consideration. In brief, the available facts suggest that the spores of *B. botulinus* may gain access to canned foods. The toxins and bacilli are easily killed by heat, the spores are exceptionally resistant, and some are likely to survive any processing given. While most succumb to reasonable temperatures (45 minutes at 105° C.), more resistant strains are known which require six hours at 100° C. or 36 minutes at 110° C. to destroy them. The ingestion of fruit containing undeveloped spores probably does no harm, as they do not develop in the animal intestine. If, however, the conditions in the tin are such that they can multiply, they produce toxins and the whole tin is excessively poisonous. Fortunately the other products of growth are unpleasant and definite signs of spoilage are present. In exceptional cases these have not been noted. The risk is that while present they would be overlooked by the careless person, although definite enough to the expert. In the Loch Maree outbreak the wild-duck paste, from its nature, would tend to mask such changes, although probably they would have been noticeable to an expert. The risk of botulism from canned foods is a real, but an extremely small one, and with added care will be still further diminished. Tin poisoning from canned foods is a popular rather than a real danger. Apart from old stocks of foods, such as acid fruits, meat essences, and a few marine foods which dissolve tin, the amount present is always small and much of it in an insoluble form. There are few, if any, recent recorded cases of tin poisoning from this source.

It is not possible to give a simple direct answer to the question as to whether vitamins are present in canned foods, as so many factors are concerned. The whole complex of changes which are necessary in canning foods are detrimental to their content in vitamins, and these are particularly affected by the oxidation allowed and the temperatures reached in processing. The three types are not equally affected. Type A is comparatively heat-stable and there may be no material diminution in the vitamin content. The B type is more thermolabile and with any considerable application of heat is likely to be dangerously reduced or even destroyed. Vitamin C is still less resistant to heat, and it is probably safe to assume that it is absent in most canned foods.

Considering the subject broadly, we can conclude that while canned foods have definite and special risks of their own they are not large and are for the most part readily guarded against. Compared with fresh foods, canned foods are undoubtedly safer, and popular prejudice against them is not justified. Certain improvements in manufacture, distribution, care, and supervision are necessary, as has been pointed out, but these are not very considerable. No one who has studied the subject can be left in doubt as to the very great value to the community of this method of preservation.

TRAUMATIC INTRACRANIAL AEROCELE.[1]

BY SIR WILLIAM WHEELER, M.D. DUB.,
F.R.C.S. IREL.,
PRESIDENT, ROYAL COLLEGE OF SURGEONS IN IRELAND.

A FATAL case of head injury, admitted into Mercer's Hospital on Jan. 15th last, exhibited some unusual features worthy of interest.

The patient, aged 45 years, fell from a bicycle on the right frontal region. There was a small wound above the outer side of the right eyebrow, and some ecchymosis and bruising over the entire frontal region; the right pupil was dilated; there was retention of urine; blood-stained cerebro-spinal fluid trickled from the nose. The diagnosis of fracture of the anterior fossa of the base of the skull could be predicted with certainty. He was mentally confused, but he was able to swallow and to answer questions with fair intelligence.

Operation.—An hour after admission his condition was less satisfactory. The skull was opened over the right frontal lobe by means of Hudson's drill and bone forceps. On incision of the dura air bubbled out in small quantities, followed by blood-stained cerebro-spinal fluid. The general blood pressure was low and the brain correspondingly retracted. The frontal lobe of the brain appeared in no way injured, but on free exposure an unusual phenomenon was observed. The patient was breathing heavily; on inspiration the frontal lobe moved upwards from the base of the skull and fell back again on expiration. This movement of the brain synchronous with respiration was well marked.

---

[1] A communication read at a meeting of the Pathological Section of the Royal Academy of Medicine in Ireland on March 2nd, 1923.

and rendered obscure the natural pulsation. It was obvious that air under some pressure was passing from the nose through a rent in the dura, in the neighbourhood of the cribriform plate of the ethmoid and roof of the orbit. It was difficult, however, to understand how, with the dura widely opened by the operation, the force of air was sufficient to raise the brain on each inspiration; yet the movement was very distinct and obvious to all present.

The wound was closed without drainage in order to lessen the paramount danger of infection. The absorption of the cerebro-spinal fluid flowing into the areolar scalp tissues provided, in our view, a sufficient outlet for the extravasation of blood and cerebro-spinal fluid. The nose was cleaned out with alcohol and loosely plugged with sterilised wool.

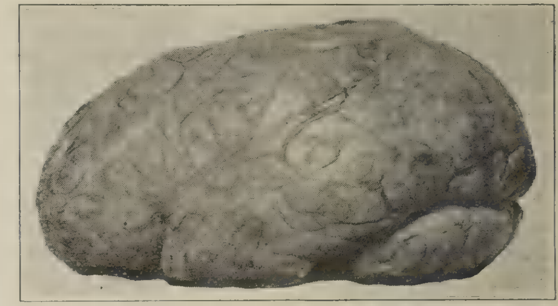
Course of Case.—The patient's condition improved considerably after operation. Hexamine was administered freely by the mouth, and small doses of hyoscine assisted in controlling restlessness and irritability which at times increased to a state of violence. Six days after operation the temperature rose to 102° F.; the patient became unconscious; the breathing was stertorous, and the pupils were dilated. The right pupil was still slightly larger than the left; both reacted to light, and there was a faint conjunctival reflex. 30 c.cm. of turbid fluid, containing a pure culture of pneumococci, was withdrawn by lumbar puncture by Dr. Milne Henry. During the withdrawal of the fluid the blood pressure fell from 130 to about 110, and rose again about 15 minutes afterwards. The temperature continued to rise until it reached 105°, and the patient died of meningitis on the eighth day after operation.

Remarks.

Since this communication was written, a paper has appeared by Grant, of Philadelphia,[2] on Intracranial Aerocele following fracture of the skull. He states that reliable authorities have spoken of the condition as "pneumocranium," but objection is taken to this term as having no definite meaning. "Pneumocele" or "aerocele" connotes a swelling or tumour containing air; "intracranial" localises the position of this air, and, as it always follows injury, the word "traumatic" may be added with advantage. He states that trauma of the frontal region of the skull involving the sinuses, a compound comminuted fracture resulting in a tear of the dura which permits the ingress of the air, is the commonest cause of the condition; but any compound fracture with a dural tear, whether the sinuses are involved or not, may be followed by the formation of an aerocele. The air is always intradural.

Grant points out that the presence of intracranial air may not be suspected until shown by a rontgenogram. He finds ten recorded cases of the condition in recent years, and in six the aerocele developed insidiously, and was found by X rays at intervals varying from a few days to several months after injury. In some cases the injury was comparatively trivial. In our case the patient was admitted at night and operated upon within an hour of admission, so that no X ray examination was made. In Grant's case the injury appears to have been almost identical, but on the left side. In both cases the pupil was dilated on the side of injury, possibly owing to some involvement of the third cranial nerve, but more likely—in the absence of other ocular signs—to stimulation of the sympathetic, and at operation air escaped in small quantities when the dura was incised. In Grant's case subsequent X ray examinations showed no increased density due to the presence of air, and it was concluded that the rent in the dura closed spontaneously. The literature on the subject suggests that, owing to the danger of infection in these cases, the presence of aerocele immediately following injury is an indication for operation, and Grant thinks that an attempt should be made to close the dural tear. If five or six days have elapsed, and the aerocele is discovered in a photograph by accident, the sinus may have spontaneously closed and the policy of watchful waiting for absorption should be instituted. Air, per se, once the possibility of infection can be excluded, is relatively innocuous and will be ultimately absorbed. In nine of the ten cases collected by Grant injuries to the scalp were noted in the region of the eyebrow. In four no operation was performed; two of these recovered and two died—one six months after injury. Of the remaining six, four died; in one a cyst containing air the size of a hen's egg was found, and three succumbed to meningitis.

In making the diagnosis of fractured base of the skull, it is convenient to consider the signs in three classes—certain, probable, and uncertain. If cerebro-spinal fluid escapes from the nose, ear, or mouth, a fractured base is certain; in rarer cases brain matter may be extruded, which also renders the diagnosis certain, and a third certain sign may now be added—i.e., the demonstration of an aerocele by a skiagram. Of the "probable" signs, first importance should be attached to injury to the cranial nerves. The "uncertain" signs are numerous; those most obvious being ecchymosis, appearing late, and often preceded by bleeding from the ear and nose or mouth. The mental condition of a patient varies to such an extent in all head injuries that it is only of diagnostic importance when considered in conjunction with the other factors.



From a photograph showing obliteration of the sulci by the exudate. This is well marked in the neighbourhood of the Sylvian fissure. Some of the thrombosed vessels are also visible. (See post-mortem report.)

The points of interest in the present case are: (1) The intradural presence of air; (2) the rise and fall of the frontal lobe with respiration, which was well marked, but difficult to explain; and (3) early dilatation of the pupil on the side of injury without other ocular signs, in the absence of compression and before the onset of meningitis.

In view of the high mortality from infection to the meninges in fractures of the base of the skull communicating with the external air, and notwithstanding the general trend of opinion in favour of operation, it seems questionable whether treatment along conservative lines would not be followed by better results. Prophylaxis in the form of careful attention to the orifice through which blood and cerebro-spinal fluid are escaping, and the administration of urotropine and its derivatives, will tend to prevent infection better than drainage. To search for and close the rent in the dura at the site of a basal fracture, as suggested by Grant, in many cases would be a procedure of great mechanical difficulty and danger; furthermore, intradural air, per se, as already stated, is innocuous and rapidly absorbed. The great difficulty is to be certain beforehand that no compression, laceration, or controllable hæmorrhage exists, in addition to the fracture and the subdural air.

Post-mortem Report, by Dr. E. C. Smith.

On Jan. 21st about 10 c.cm. of cerebro-spinal fluid were received for examination from the above case. The fluid was cloudy and contained a copious white sediment. Cultures were made on blood-agar. Smears of the sediment, when stained by Gram, showed numerous polymorphs. Large numbers of Gram-positive cocci in pairs were also present. On the following day (22nd) the plates showed a pure growth of pneumococci. The colonies were greenish, and some hæmolysis was visible. The cocci were bile-soluble. The brain was exposed by extending the operation wound and removing the calvarium.

---

[2] Surgery, Gynecology, and Obstetrics, February, 1923.

The quantity of cerebro-spinal fluid was much greater than normal. It was distinctly turbid. The surface of the brain was covered with a purulent exudate which obliterated the sulci. The exudate was most marked anteriorly (see figure). Many of the meningeal vessels stood out prominently and felt very firm, apparently thrombosed. Direct smears were made of the exudate and stained by Gram. Numerous pus-cells and Gram-positive diplococci were present, some of the latter had well-marked capsules. When the brain was removed, a fracture, extending through the right side of the ethmoid bone and involving the sphenoid, was apparent. When a probe was passed down from the fracture it appeared at the anterior nares.

SURGERY IN THE TREATMENT OF PULMONARY TUBERCULOSIS.

By CLIVE RIVIERE, M.D., F.R.C.P. Lond.,
PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST;

AND

W. H. C. ROMANIS, M.C. Camb., F.R.C.S. Eng.,
SURGEON TO THE ABOVE HOSPITAL; ASSISTANT SURGEON TO ST. THOMAS'S HOSPITAL.

(With Illustration on Special Plate.)

Just over 100 years ago, in the year 1822, the following remarkable sentence was written on the subject of pulmonary tuberculosis: "It has long been my opinion that, if ever this disease is cured, and it is an event of which I am by no means disposed to despair, it must be accomplished by mechanical means, or, in other words, by a surgical operation." James Carson, the writer of these words, had recognised that the obstacle to the healing of lung disease lay largely in the "elasticity and condition of extension" of the organ—as soon, he said, expect healing in a divided tendo Achilles without mechanical help! But if the lung were allowed to collapse "the diseased part would be placed in a quiescent state, receiving little or no disturbance from the movements of respiration, which would be performed solely by the other lung, and the divided surfaces would be brought into close contact by the same resilient power which before had kept them asunder. A wound or abscess in this lung would be placed in circumstances at least as favourable to the healing process as the same affections in any other part of the body." The principles which are here so clearly enunciated led, after many years, to the collapse therapy (artificial pneumothorax) which Carson urged, and also to thoracoplastic operations (de Cerenville, 1885; Quincke, 1888; Lucius Spengler, 1890) designed to the same end—namely, the collapse and immobilisation of the diseased organ. The simplicity and safety of artificial pneumothorax, and the success which has attended it, necessarily makes this the first choice in cases where collapse and immobilisation of the lung seem indicated.

Indications for Artificial Pneumothorax.

At this point it may be useful roughly to state the indications for collapsing a tuberculous lung by artificial pneumothorax. It is where disease in one lung is judged to be getting, or to have got, too bad for recovery by ordinary sanatorium treatment, and where the other is judged sufficiently "good"—in a tuberculous connexion—to function alone. In all cases where collapse of a lung is indicated artificial pneumothorax will first be attempted; indeed, it may be said that in practice other surgical procedures wait upon artificial pneumothorax, and that only where this, after due trial, has failed of full attainment are other methods admissible. The only exception one is tempted to make to this general rule is where strictly localised disease demands localised collapse, and where the collapse of a whole lung seems a large price to pay for its attainment. To this we will return.

The difficulty which surgery is, in practically all cases, called on to overcome is adherent pleura, the visceral and parietal pleuræ becoming adherent to each other in very varying degrees. There are two types of adherent pleura which demand surgical interference: (1) Those where a limited number of thick, firm, rounded, fleshy adhesions, often one or two inches long, connect the two layers of pleura, often dragging out with them and into themselves portions of lung tissue; and (2) those where the two pleural layers are more or less completely fused together and no free space can be found.

Separation of Pleural Adhesions.

An artificial pneumothorax is seldom entirely complete at the beginning; the pleural surfaces adhere commonly at a few points, and in some cases at many. As a rule these adhesions separate or stretch in course of time, and an efficient pneumothorax is eventually obtained. If, on the other hand, large areas of lung are closely adherent, only a partial pneumothorax, whether "effective" or not, is obtainable. Between these two conditions occur cases, uncommon in our experience, where "effective" collapse is prevented by strong, fleshy bands. When these are few and not too thick they may be successfully separated by the electro-cautery with the aid of a thoracoscope (Jacobaeus, Saugman, &c.), or divided with a tenotome (Morriston Davies). In the following case numerous strong adhesions, rendered thicker and shorter by a seroplastic pleurisy, were divided as a last resort by open operation.

Case 1.—Female, aged 24. Advanced disease of left lung with extensive cavitation, a good deal of quiet or healed disease in right lung to X ray examination. Pneumothorax (left), May 8th, 1920, but lung held out by numerous adhesions, though surrounded by gas. These were easily seen in the X ray plate. Pneumothorax persisted in, with some stretching of adhesions, up to October, 1920, when a pleurisy occurred and was followed by rapid shortening of the adhesions and re-expansion of the lung. On May 7th, 1921, left pleural cavity opened without removing a rib through third intercostal space, and seven firm, thick adhesions divided with scissors and cautery—some of the thickness of a Fallopian tube—also a wide sheet of adhesion at apex. Pericardium also adherent and left so. Operation took 23 minutes, performed under gas and oxygen, and well borne by patient. Followed by but slight reaction, but much cough and sputum occurred as the lung collapsed. some blood-clot accumulated at base of chest, and some crepitations appeared in right interscapular region, but had gone again by May 25th. Small fillings of gas were given on the 14th (pressure raised to +5 without leakage), on the 19th to +14, 25th to +18, and by June 22nd to +30 mean. By this date (June 22nd) she appeared to have regained her strength, and her weight (8 st. 5¾ lb.) was 1¼ lb. higher than in April before the operation. Progress appeared to be maintained till mid-July, when a tuberculous abscess in the scar led to a fistulous opening into the pleural cavity, and at the same time signs of disease appeared over the right lung both back and front. Now, some 18 months after the operation, she is still living, but in poor health, with some fever present, and with an open sinus. The chance of permanent success having failed, it can at most be claimed that life has been prolonged by the operation.

Opening the pleural cavity under these conditions is a fairly severe proceeding, but the alternatives of pneumolysis and thoracoplasty would have been equally so, and would have equally threatened a breakdown of the functioning lung. It is inconceivable that all these adhesions could have been separated with cautery or tenotome. With separation by open operation, which is easily done under gas and oxygen, and without resecting any part of a rib, the danger of hæmorrhage from the cut adhesions, which is undoubtedly present in the first two (closed) methods, does not exist, for the cut ends of the adhesions can be seen, and ligatured or cauterised should any bleeding be present. It is essential, when these adhesions are cut, to cut them as far away from the lung and as near the ribs as possible, for in the central ends of thick and fleshy adhesions there may always be small portions of infected lung tissue, which if exposed will quite possibly infect the pleural cavity.

Stripping of Parietal Pleura from Chest Wall.

Where adherent pleura entirely prevents the formation of a pneumothorax, surgical measures may be undertaken to collapse the lung within the bony thorax. Attempts have been made from time to time to separate adherent pleural surfaces, but these are to be condemned as difficult or impossible. Quite easily, on the other hand, can the parietal pleura be stripped from the deep fascia and ribs outside it, and thereby the lung allowed to collapse within the chest wall. The cavity thus formed must be duly filled if the lung is to remain collapsed, and here arises the problem with regard to "pneumolysis" as the operation is called. The space may be filled with a solid medium, such as sterile paraffin wax or adipose tissue, as was originally done by Tuffier, with whose name this procedure is associated, or gas (air or nitrogen) can be tried, and an extrapleural pneumothorax instituted, as has been done of recent years. We have made some trial of both methods, as the following cases testify.

Paraffin Replacement.

In the following cases paraffin replacement was attempted.

CASE 2.—Male, aged 29. Localised, old cavitation at right apex, with only slight activity around, but recurrent hæmoptysis; sputum, an egg-cupful daily, containing tubercle bacilli. On May 27th, 1920, under gas and oxygen, an incision was made in third intercostal space; no rib was removed, and the parietal pleura was gently stripped from the chest wall over the apex and upper third of the lung, the resulting cavity being filled with paraffin wax. The operation took 20 minutes altogether, and was followed by little temperature and reaction (a single rise to 100°), no after pain, and only slight surgical emphysema. By July 13th his weight was 3½ lb. higher than before operation, and his sputum greatly reduced. Thereafter he kept well till Sept. 10th, when a fluctuating swelling formed in the scar and was opened by his doctor; 4 oz. of serous fluid escaped, and thereafter wax began to come away. This continued up to January, 1921, when the sinus healed, and by then slight cavity signs had reappeared, though the patient kept well all through this time, and was at work. In November more paraffin was extruded. The patient continues in good health and has had no hæmoptysis since the operation. The sinus remains closed.

CASE 3.—Male, aged 30, sent to us in May, 1922, by Dr. Christopher Rolleston, with chronic disease of right lung and cavitation outside the right root at level of sixth rib behind. Left lung old and inactive (?) disease. Repeated severe hæmorrhages (up to 2 pints on one occasion) were the main complaint. Artificial pneumothorax having failed of establishment both in Dr. Rolleston's hands and in our own, on July 26th an incision was made in the third intercostal space on the right side, and without any removal of rib the parietal pleura was stripped from the endothoracic fascia over a large area, including the apex, extending well down to the root: the resulting space was packed with paraffin. The third and fourth ribs were wired together to close the opening more effectually. Considerable febrile reaction followed the operation (temp. to 101° and later to 100°), and lasted a little over two weeks; during this time patient looked ill and lost weight. No immediate increase of sputum occurred. On Sept. 15th a fluctuating swelling appeared in second space above the scar, and some serous fluid was removed with a needle and syringe, and again on one occasion since, but the wax has been retained. His present condition is pretty good, but he has had one slight hæmoptysis since the operation.

Air Replacement.

In the following cases air replacement was attempted.

CASE 4.—Female, aged 24. Disease of whole right lung with extensive cavitation, the left lung being a fairly good organ. Attempts at pneumothorax treatment disclosed a totally adherent pleura, and on Jan. 6th, 1921, an incision being made in the right third pleural space without any removal of rib, the parietal pleura was stripped from the endothoracic fascia over nearly the whole lung, including the entire apex; the resulting cavity was left full of air and the incision carefully closed. It was intended to refill this cavity at the end of a week, but unfortunately this period was inadvertently lengthened to 12 days, and then attempts to put in gas entirely failed, the lung having re-expanded and the space having become obliterated. Absorption of air from the raw surface seems to be rapid, and we now think a week would have been too long: refills should have been begun a couple of days after the operation. The operation appeared to stimulate fibrosis in the underlying lung, and for a time the patient appeared to improve, but this was not maintained, and the patient now has extensive and irremediable disease almost throughout both lungs.

CASE 5.—Young female, sent to us by Dr. Rolleston after two attempts, unsuccessful owing to adhesions, to induce a pneumothorax. There was very advanced disease of the left lung, with extensive cavitation near the base, and a hectic temperature. The right lung appeared sufficiently good. Under gas and oxygen the chest was opened through the third intercostal space, and the pleura stripped off the ribs for the whole of the upper three-quarters of the lung. The wound was resutured with a valvular tube in it which would let air into the chest but not let it out, the air being carefully filtered through sterile wool first. It was hoped that by this means we should be able to keep the lung collapsed. Severe surgical emphysema developed, which disappeared a few days after the tube was removed. On the eighth day 900 c.cm. of air were introduced, and, later, subsequent fillings, but the wound did not remain air-tight, the temperature kept up, and the patient got worse. She died about seven weeks after the operation; post-mortem examination disclosed active disease in both lungs and suppuration of the extrapleural cavity.

Thoracoplasty.

It has been rather presumed up to this point that the surgical operations designed to extend or replace a pneumothorax possess the same "indications" and "contra-indications" as does artificial pneumothorax itself. This is, however, not entirely the case even with the measures already discussed, and it becomes still less so where a thoracoplasty is concerned. The separation of adhesions and pneumolysis do indeed but aim at a lung collapse within the bony thorax, but they are more serious measures than an ordinary pneumothorax, for the following reasons: (1) Operative measures are a strain on recovery in any case of tuberculosis, and this must be taken into consideration; (2) the lung collapse, instead of being slowly brought about, is, so far as it occurs, immediate, with the result that there is more mechanical and toxic disturbance, and more risk of aspiration pneumonia or tuberculosis in the better lung or in uncollapsed portions of the bad lung; (3) the collapse is less remediable than in pneumothorax therapy, where in most cases the lung can be re-expanded (to a varying degree, it is true) at the end of treatment, or—a most important point—if trouble threatens in the other lung.

These objections, applicable to some extent to the "pneumolysis" type of treatment, hold still more decidedly in the case of thoracoplasty. Here, in particular, the third point, the irremediability of collapse, has to be especially borne in mind. An exacerbation in the other lung must here leave us helpless, and this knowledge especially forces on our recognition the main difference between the indications for these operations and those accepted for pneumothorax treatment. This difference lies in the condition of the functioning lung. For pneumothorax therapy this organ must be a good one; that it is diseased is almost a sine qua non, but the disease must not be active, or, even when quiet, severe. But in pneumothorax therapy some latitude may be allowed in this respect, on account of the fact that treatment can be abandoned at any moment and the collapsed lung allowed to re-expand; this will often allow an exacerbation in the functioning lung again to become quiescent. For operative measures, and especially for thoracoplasty, from which there is no return, the condition of the better lung must be much more meticulously examined, and the operation rejected in some cases where a pneumothorax might reasonably be attempted. Great experience, particularly "pneumothorax" experience, is needed in this decision, and good radiograms are essential for the purpose. Many continental authorities are of opinion that no cases of rapid spreading or caseous tuberculosis should be submitted to thoracoplasty; they consider that evidence of a healing tendency as shown by lung retraction must be present, and prefer the operation especially for old cavity cases with fibrosis. This is probably to limit its application too severely; each case must be considered on its merits, with due recognition of the fact that it is often a question of giving a chance of life in a case with an otherwise hopeless outlook.

As to the amount of lung collapse achieved by thoracoplasty, Brauer has put it, at highest, at three-quarters of the collapse obtained by an artificial pneumothorax. But Dumarest considers that the apex of the lung is always less collapsed than this. Thus thoracoplasty may be said to correspond in value to a good partial pneumothorax, less the operation shock and the mutilation, which last is much slighter than might be expected. To be weighed against these are the facts that the patient avoids pleural complications and the trouble of refills. The results may be, and often are, excellent, though in some cases the collapse may prove insufficient, and after an interval of arrest disease may again break out and spread. Of 381 thoracoplasties performed by Sauerbruck, 134, or 35 per cent., are claimed as "cures"; the post-operative mortality amounted to 2 per cent. (mostly in the Brauer-Friedrick operation, which was performed in 71 of Sauerbruck's cases); 12 per cent. died during the first three weeks from aspiration pneumonia and tuberculosis of the better lung. When it is remembered that the material selected for thoracoplasty consists of cases severe and otherwise generally hopeless, it must be admitted that these results are very decidedly encouraging.

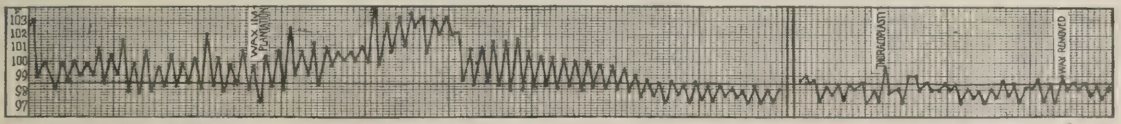
The operative measures covered by the term thoracoplasty are many and various, and may be shortly classified as follows:—

1. *The Brauer-Friedrick Operation.*—Through a paravertebral incision carried round the base and up the front, large amounts of the first ten ribs are removed, rising to 10–25 cm. of the lower ribs. This operation is very severe and has been followed by a higher immediate mortality than the others.

2. *Sauerbruck's Operation.*—Paravertebral resection of all the ribs with removal of 6 or 8 cm. of each rib close up to the spine. The technique of Saugman is closely similar. Both operators work under local anæsthesia.

3. *Wilms' Operation.*—Removal of pieces of eight upper ribs behind, and three or four weeks later a similar removal in front.

4. *Partial Thoracoplasty.*—From the fourth rib down, as was originally done by Sauerbruck; or the upper part anteriorly, the first to fifth ribs, as used by Sauerbruck if activity remains at the apex after his paravertebral operation.



Temperature chart of Case 6, showing times of wax implantation, thoracoplasty, and removal of wax.

5. *Combined Thoracoplasty and Pneumothorax.*—Here an adherent apex with a pneumothorax below is collapsed by removal of portions of the upper five to seven ribs.

6. *Thoracoplasty Combined with Section of the Phrenic Nerve.*

We have considered carefully the relative merits and demerits of the two operations of thoracoplasty and pneumolysis with paraffin packing; they are procedures similar in some ways, in that they are both elaborate operations and both aimed at collapsing the lung, and yet totally dissimilar in other respects. Thoracoplasty, however performed, is the more severe, producing more shock, reaction, mutilation, and deformity than does a stripping of the lung with paraffin displacement, for this latter is easily performed in 25 minutes between two ribs without excising any bone at all. Nevertheless, severe cases of phthisis appear to withstand the shock of an extensive thoracoplasty remarkably well, and we have come to the conclusion that thoracoplasty is on the whole a better operation than paraffin implantation. Paraffin wax is apt to give trouble, tending to extrude itself through the wound some months after operation. This extrusion is generally heralded by the appearance of serous fluid under the skin at this spot, and if this is aspirated through a fine needle the danger may be averted; if wax comes away, the wound, nevertheless, ultimately heals quite satisfactorily. In thoracoplasty this source of trouble is avoided; moreover, its ultimate results should prove better than those of pneumolysis, for though a wax implantation within the ribs may produce efficient collapse and compression, it does not limit the mobility of the hemithorax as does extensive removal of the overlying ribs.

In the cases we have treated hitherto, thoracoplasty has been performed on the lines of Saugman's operation, large portions of the ribs being removed from behind through a single J-shaped incision, always including a portion of the first rib, and usually going right down to the ninth or tenth ribs; this allows of an extensive falling in of the scapula and chest wall, with corresponding collapse and immobilisation of the lung. Saugman lays stress upon the necessity of performing the operation with a local anæsthetic, and in many cases of doing it in two stages. Neither of these have been thought necessary or advisable in our cases. The question as to what is the best anæsthetic to give in phthisical cases has often been discussed; we have come to the conclusion that, although theoretically local anæsthesia is preferable, in practice gas and oxygen, without any ether or chloroform, is just as safe and very much more pleasant for both patient and surgeon. We have been fortunate in having the assistance of Dr. L. W. Shelley to give the anæsthetic in these cases, all of which have been done under gas and oxygen, and in no instance has the anæsthetic caused any anxiety.

We have not, so far, performed the operation in two stages, though in every case we have been quite prepared to do so if necessary, but the patients have stood the procedure of extensive rib resection so remarkably well that it has in every case been possible to complete the operation in one sitting, usually in about 35 to 40 minutes. The operation of section of the phrenic nerve in the neck to produce paralysis of the diaphragm and thereby induce collapse of the base of the lung, has, of course, frequently been performed, as a rule without very much success, but in three cases we have performed it as a supplementary procedure after thoracoplasty. It probably diminishes respiratory movement at the apex as well as at the base (Keith). It is in itself a trifling procedure, by means of which not only may the collapse be made more complete, but it may not be necessary to remove quite so many of the lower ribs.

CASE 6.—Female, aged 22, had a pneumothorax started in a provincial town in September, 1919, for acute tuberculous disease of left lung; this was continued with most successful results for two years. At the end of this time, however, the lung inadvertently expanded and became attached to the chest wall, and the pneumothorax was unfortunately abandoned. In a couple of months fever and other symptoms returned, and she was sent to one of us to try to re-establish the pneumothorax. This failed, and since under complete rest the fever only increased, signs of disease spread, and she was rapidly losing ground, on April 27th, under gas and oxygen, the parietal pleura was stripped over the upper half of the left lung, through the third intercostal space without removal of rib, and the resulting space packed with paraffin. Unfortunately the cavity suppurated, and wax soon began to extrude through two openings. The temperature remained high for nearly six weeks, at the end of which time it fell to normal; sputum fell, after a temporary increase, from 1 oz. to 1 drachm, and she started to gain weight rapidly, though the cavity still suppurated (*Staphylococcus albus* was cultured), and the wax continued to extrude. Finally, as the wax was being lost rapidly and symptoms of tuberculous toxæmia began to return, it was decided to do a thoracoplasty while the patient's condition was still favourable, her weight having risen 8 lb. since the first operation. This was done under local anæsthesia, followed by gas and oxygen, on August 26th through a paravertebral J-shaped incision, portions of first to tenth ribs, inclusive, being removed without any opening being made into the anterior suppurating cavity. The operation was followed by practically no reaction, and the wound healed by first intention. Soon afterwards the remaining wax was removed, and with no further expansion of the lung the cavity quickly contracted from falling in of the chest wall. At present she has a normal temperature, a trace or less of sputum, gains weight, is up some hours daily, and looks fat and well. The sinus is now a shallow opening, which the skin is rapidly covering. Her temperature chart is here given.

Case 7.—Female, aged 24, sent to us in August, 1922, by Dr. Christopher Rolleston, with active and spreading disease of left lung and failure to produce pneumothorax. A further attempt by us also disclosed adherent pleura, and complete rest produced no effect on the continuous fever. A radiogram showed rather ominous mottling round the right hilum as well as active disease in left. In view of the otherwise bad prognosis it was decided to do a thoracoplasty, and this was carried out on Oct. 3rd under gas and oxygen, portions of first to ninth ribs being removed through a paravertebral J-shaped incision. In all 24 inches of rib were taken away, the operation lasting 45 minutes from start to finish, and being well borne by the patient. It was followed by but moderate dyspnœa and discomfort, but a considerable reaction, the temperature rising to 102°–103°F., and falling, practically, by crisis on the ninth day. Thereafter it remained normal for nearly two weeks, and the patient looked, felt, and ate better. After this the temperature began to rise to 99°, and later to 100°, and the patient felt tired and not so well. A certain amount of air-entry was found at the base of the collapsed lung, and with a view to stopping this the phrenic nerve was cut in the neck under a local anæsthetic on Dec. 13th. The lung base has now collapsed completely. The X ray photograph reproduced (see special plate) shows the condition of this patient's chest after the operation. The operation of cutting the phrenic nerve is a trifling one, and it is possible that in many cases it might be wise to combine the thoracoplasty with a phrenicotomy.

Case 8.—Female, aged 38, treated for pulmonary tuberculosis at intervals since 1917. Chronic disease with cavitation in left lung; right lung arrested disease. Troublesome febrile periods and "congestive attacks." Pneumothorax treatment (by Dr. J. M. Johnston, of Tor-na-Dee Sanatorium, Aberdeenshire) failed owing to adherent pleura. On Nov. 28th, 1922, under gas and oxygen, portions of the first nine ribs on the left side were removed through a paravertebral incision, about 39½ inches of rib altogether, including 1½ inches of first rib. The operation lasted 35 minutes and was well sustained. This patient had remarkably little reaction. Before operation she had had periodic rises of temperature about every three weeks, but since the third day after operation there has been no rise of temperature at all. The chest has fallen in considerably, and there is very little air-entry on the diseased side; at present she looks and feels remarkably well.

Conclusions.

In summing up the experience gained by the treatment of the foregoing cases, and by a consideration of the whole problem of surgical assistance in pulmonary tuberculosis, we are led to the following conclusions:—

1. Chest operations rapidly and skilfully carried out under gas and oxygen are remarkably well tolerated by tuberculous patients, much better than preconceived ideas would have suggested. We incline decidedly to gas and oxygen in preference to local anæsthesia.

2. We are in favour, so far as possible, of extrapleural operations, in preference to the intrapleural division of multiple adhesions.

3. Of extrapleural operations the stripping of parietal pleura from the deep fascia (pneumolysis) is the simplest and shortest, provided a suitable medium could be discovered for filling the space. It has the advantage that localised collapse can be applied to localised disease, without the necessity of complete lung collapse.

4. Pneumolysis is undoubtedly accompanied by real risk of sepsis, and Tuffier, its originator, was concerned to devise special measures for its avoidance. The establishment of an extrapleural pneumothorax is somewhat difficult and not without risk; adipose tissue, as a filling, is difficult to obtain; paraffin is apt to be returned. This latter accident is probably avoided, in threatening cases, by the aspiration of serous fluid, which tends to be formed and to collect round the paraffin in these cases.

5. The efficacy of paraffin replacements is probably reduced by the fact that no such immobilisation of the collapsed area occurs as after extensive rib resection. Furthermore, the localisation of the collapse is also, probably, less than might be hoped for.

6. For the majority of cases in which operative measures are needed for the collapse and immobilisation of an adherent tuberculous lung, a well-devised thoracoplasty seems to us to offer the best results. The operation is less severe, in skilful hands, than might be expected, and the conditions obtained are very favourable for the arrest of pulmonary tuberculosis. The better lung must be scrupulously investigated, and the best moment chosen for the operation. A reactivation on the side of operation may be met by further resection of ribs (see No. 4 in list of classified thoracoplasties), but an extension of disease in the functioning lung admits of no alleviation. This operation, if indications and contra-indications are strictly followed, is likely to gain a wider acceptance in coming years.

A CASE OF
SYPHILIS OF THE MEDIASTINUM.

By HAROLD F. RENTON, M.D., B.S. Lond., M.R.C.S. Eng.

(*With Illustration on Special Plate.*)

In order to give a complete and concise account of the following case the personal history over a period of five years has been submitted.

First Period of Observation.—In February, 1917, I was called in to see a young woman, aged 18 years, who was said to be suffering from rheumatism. Examination showed both knees to be swollen. These were not inflamed, and were quite painless. There was no temperature and no sore throat, and no evidence of rheumatic fever. Generally distributed about the abdomen and the anterior aspect of the arms and legs there was a macular rash, brown in colour, and typically syphilitic. The patient was given generous doses of mercury, and the whole condition cleared up.

Second Period of Observation.—Early in 1919 the patient, now married, gave birth to a healthy, full-term child, but in 1920, at the beginning of the year, another child was born. This one was covered with pemphigus, and presented all the appearances of congenital syphilis. Despite treatment the child died. In the same year the patient came for advice, complaining of sore throat and difficulty in swallowing. Examination revealed the presence of a typical gummatous ulcer on the posterior pharyngeal wall. This was as large as a shilling and covered with a grey slough. Large doses of iodide of potassium with mercury were administered with excellent results, and once again the patient recovered. It should be noted here that, as is so common in similar cases, the patient ceased her treatment as soon as she began to feel better.

Third Period of Observation.—In August, 1921, the patient noticed that her left eye was swollen; the left upper eyelid had dropped, and that she could not raise it. She also

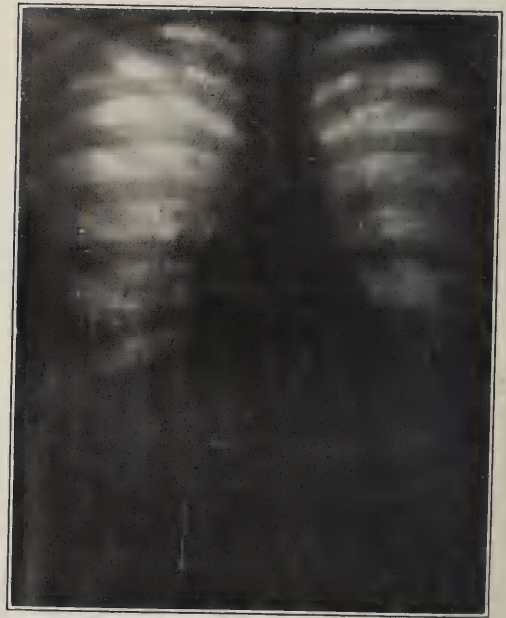
Scattered tuberculosis in both lungs. The arrows show in descending order: (1) Fibrous band; (2) cavity; (3) adhesion of diaphragm.

14



A case showing no evidence of tuberculous disease, but revealing fixation of the diaphragm as a result of pleurisy.

began to suffer from pains down the left arm. These began in the shoulder, and extended down the arm, with tingling in the two middle fingers. In the middle of September the voice became husky, but there was no cough. The patient said that she dare not cough because of pain in the throat. She had lost some weight, and complained of pain in the chest, which she thought was due to indigestion. She noticed that her food passed so far down her gullet and then seemed to stop, afterwards moving on with a great "belch" of wind.

Condition on Examination.—Eyes: Left palpebral fissure much narrower than the right. Marked ptosis and loss of power of left upper lid; left eye movements good, but adduction rather feeble; both pupils react to light and accommodation, and both fundi normal. Arm: No wasting, left hand rather cold, but all movements good; left pulse very feeble, almost impalpable and markedly delayed. Chest: Some dilated veins over left chest in front, stretching outwards and downwards towards the left shoulder; no pulsation, obvious or palpable, and no thrill; marked dullness of the front of the chest, commencing at the level of the second right costal cartilage, extending downwards to the fourth costal cartilage of the same side, sharply defined to the right by the sternal margin, and extended outwards across the sternum to the left side for a distance of two inches from the midsternal line; above, this area was bounded by a line joining the second right and third left costal cartilages, and below by a line joining the fourth right costal cartilage and the apex beat; there was no dullness elsewhere, and no adventitious sounds. Heart: Not enlarged and not dislocated; there were no murmurs, but the sounds were rather "tic-tac" in character. Larynx: Showed paralysis of the left vocal cord. There was no tracheal tugging, and no enlarged glands were to be felt above the clavicle or in the axillæ. Sputum examination, made on several occasions, showed no tubercle bacilli. Blood examination gave a positive Wassermann reaction in very free dilution. X ray examination revealed distinct widening of the root of the aorta, suggesting some early dilatation, probably the result of syphilitic aortitis. Very marked mottling and fibrous striation at the roots of the lungs could also be seen. The remainder of the lungs appeared clear and filled well on deep breathing. Post-sternal shadow was rather dense.

Progress of Case.—Very large doses of iodide of potassium and mercury were administered and mercurial inunction performed, and the eye disturbances completely cleared up. There was also marked improvement for a while in the dysphagia and in the voice. The improvement, however, was not sustained, and after a while the patient was compelled to take to her bed. Administration of salvarsan was offered and refused. Dysphagia became steadily worse, and soon the patient could not swallow at all. Dyspnœa and stridor now appeared. With this the left chest showed signs of deficient aeration, though the percussion note remained good (pressure on left bronchus). Later, wet signs developed on the left side, and the patient began to spit most foul-smelling phlegm, which was occasionally streaked with blood. This was attributed to early bronchiectatic change. The right chest, which hitherto had remained clear, now showed evidence of passive congestion, and with the onset of wasting and drenching sweats, the patient sank rapidly and died on Jan. 7th, 1922.

Diagnosis and Remarks.

When the patient came again under observation in August, 1921, her symptoms and the physical signs discovered in her chest were almost diagnostic of aneurysm of the arch of the aorta, and only the patient's age and sex of the individual and the extent of the mischief prevented such a diagnosis being made. The possibility of the presence of a mediastinal sarcoma was considered, but there was no displacement of viscera, and no obvious wasting until late in the disease. Moreover, there was marked improvement in the symptoms under antisyphilitic treatment, an improvement which could not be explained by the frequent temporary arrest of malignant growth under the exposition of iodide of potassium. That the patient was suffering from a very malignant form of syphilis there was no doubt, and whilst the possible presence of a sarcoma was admitted, a diagnosis of syphilis of the mediastinum would seem to be correct. Mr. Harold Collinson, of Leeds, who examined the case in consultation with me, concurred in the opinion formed. He also pointed out the undoubted widening of the root of the aorta, as shown by the X ray photograph. (See special plate.) Unfortunately a post-mortem examination could not be obtained.

X RAY EXAMINATION OF THE CHEST.

By BERNARD HUDSON, M.D. CAMB.,
M.R.C.P. LOND., S.F.D.,
MEDICAL SUPERINTENDENT, ENGLISH SANATORIUM, MONTANA, SWITZERLAND;

AND

PERCY G. SUTTON, M.S.R.,
MEMBER OF THE RONTGEN SOCIETY; RADIOGRAPHER, ENGLISH SANATORIUM, MONTANA.

(*With Illustrations on Special Plate.*)

IN this article we shall direct attention to some practical points concerning X ray examination of the chest, with special reference to pulmonary tuberculosis. Our remarks are based upon experience gained in the English Sanatorium at Montana, Switzerland, during recent years.

First we will consider the X ray appearances as seen in the normal chest. This is a highly important subject, and anyone who is hoping to become expert in the interpretation of chest radiograms must first of all be thoroughly familiar with the appearances seen in the chest where there is no reason to suspect any pathological condition. The normal chest under the fluorescent screen shows two upright clear areas (which light up further on inspiration), divided longitudinally by the mediastinal shadow. On each side of this, at the root, will be seen the hila with their branch-like markings; as will be explained later, these vary considerably, and should receive careful consideration. The diaphragm is marked by two dome-like shadows at the base, the right being slightly higher than the left. These two shadows fall and rise rhythmically on inspiration and expiration. The normal lung tissue will often show a faint mottling, and it requires an experienced eye to distinguish between this normal condition and the pathological mottling due to small tubercles.

Value of X Ray Examination in Detection of Pulmonary Tuberculosis.

It is frequently said, and almost universally admitted, that tuberculosis of the lungs which cannot be discovered by careful clinical methods will not be discovered by X ray examination, either fluoroscopic or radiographic. This seems to us a very sweeping assertion; personally we have come across many cases where physical signs in the chest were entirely absent on clinical examination, and where the disease was simply suspected, owing to the individual's symptoms and general condition—cases showing, on adequate X ray examination, plain signs of tuberculosis, such as, for instance, glands and masses of infiltration around the hila, which could not be made out with any degree of certainty by clinical examination.

For instance, in a man, aged 30, under observation here at the present time, there are no physical signs of any kind to be made out, nor is there fever, cough, or sputum. The only symptom of the disease has been a loss of physical energy and of weight, yet when a radiograph (see Fig. 6) of this case was taken a cavity was clearly to be seen in the upper lobe of the left lung, very plainly circumscribed by a thin wall of fibrous tissue, but with no infiltration or solidification around it. We could cite other similar cases, and therefore we have come to the conclusion, after very wide experience in radioscopy and radiography of the chest, that although the disease, if determinable by the X rays, is very often easily to be discovered by clinical means also, there are yet certain cases of tuberculosis of the lungs which without the help of careful and routine X ray examination might easily be missed, until the disease has spread to such an extent as to render a satisfactory result from treatment very much more doubtful.

Even in cases where there is no doubt of the presence of a tuberculous lesion, and where the physical signs and symptoms are quite obvious, routine examination by the X rays may be of the very greatest value, and should be carried out in all cases. Radioscopy and radiography, in conjunction with a thorough clinical examination, will give a much more comprehensive and complete idea of the case than is possible from physical examination alone. By radioscopy can be observed the degree of expansion of the lung, the displacement (if any) of the heart, the range of movement of the diaphragm on each side, and whether that movement is free, hampered, or absent, the presence of pleural adhesions, costal or diaphragmatic, and the presence or absence of fluid. By radiography movements cannot, of course, be observed, but a more detailed picture of the actual state and extent of the lesion in the chest is given by radiography than by radioscopy alone; a very recent tuberculous lesion throws little, if any, shadow on the X ray plate, and the shadow thrown deepens with the age of the lesion and with the amount of fibrotic transformation it has undergone; thus an idea of the age, localisation, &c., of the various patches can be formed.

One of the principal uses of the X rays in pulmonary tuberculosis is when deciding as to whether or not a case is likely to benefit by artificial pneumothorax. Information is gained as to the site where puncture would probably be most successful, and as to the presence or absence of adhesions. A radiogram is also, in our opinion, absolutely necessary in order to determine whether or not the other lung is free from disease, or at any rate in such good condition that artificial pneumothorax may be reasonably attempted on the diseased side. In the after control of pneumothorax cases also radioscopy is of the greatest value: one is enabled by this means to estimate the shape and size of the cavity, whether adhesions are present, the degree of collapse of the lung, and the presence or absence of fluid. In our opinion, in every case of artificial pneumothorax regular X ray observation is imperative.

Technique.

A few practical details as to technique may here be mentioned.

Radioscopy.—Although radioscopy is one of the most important aids to diagnosis of pulmonary tuberculosis, it should always be confirmed by a radiogram, as the X ray plate is more sensitive than the fluorescent screen; it should always be borne in mind that the hard ray necessary for radioscopy will often penetrate a small early tuberculous focus, and throw no shadow of it on to the screen, but when a subsequent radiogram is taken, employing a softer ray, one finds these foci clearly marked on the plate. Of the two positions for radioscopy, recumbent and upright, the latter is undoubtedly the best, as it allows easy manipulation of the patient, and the centring of the tube is much more rapidly carried out than in the case of operating with the tube box beneath the couch. It is perhaps worth mentioning that we have found the costly and elaborate upright screening stand really unnecessary both for radioscopy and radiography of the chest. A simple piece of apparatus used by us, and which can be made in the workshop at the cost of a few shillings, consists of a wooden screen of the same thickness as the X ray couch top, and can be either hinged to one end of the couch so that it can be swung up into position when required or placed in sockets; the tube stand is then moved up close to the screen and the tube box rotated for the upright position.

Radiography.—For the reasons mentioned before, it is important that a soft tube be used in radiography of the chest. Many radiographers seem to forget that the radiogram showing plenty of bone detail, although very pleasing as a picture, is absolutely worthless from a diagnostic point of view, as it is not bones but lung which one wishes to see. Therefore the tube should not back up more than a four-inch spark-gap, between points, if a radiogram of diagnostic value is to be obtained. In radiography of the chest the exposure should be extremely short, for the slightest movement of the lung will absolutely ruin a radiogram; and with phthisical subjects, as it is an extremely difficult matter for them to hold their breath for any length of time, it is important that the exposure does not exceed two seconds at the outside.

Descriptions of Radiograms.

In order to point out the great value of X ray examination in pulmonary disease, a series of radiograms has been chosen to illustrate various interesting points in this connexion.

Figs. 1, 2, and 3 are all radiograms taken of chests of completely normal persons, who have never had any sign or symptom of disease. Fig. 1 is of a lady of 40 years of age; Fig. 2 of a young man, aged 22; and Fig. 3 of a man, aged 28. What we wish to point out in publishing these three radiograms—and the greatest care has been taken to secure good radiograms of healthy individuals—is to show how very clearly and prominently the hilus of the lung stands out. There is a great tendency on the part of many to diagnose hilum tubercle on appearances such as these; the greatest care must be taken concerning such a diagnosis, especially in the absence of very clear symptoms; it is not right to diagnose tuberculosis on appearances such as these, as it is quite possible by so doing to convert a reasonably healthy person into a neurasthenic, and spoil his whole life. Another point to notice is that in a well-taken radiogram there is considerable mottling to be seen in the normal lung, and this has to be carefully distinguished from the mottling due to the presence of small tubercles. Mottling is in itself not necessarily a sign of tuberculosis.

In Figs. 4 and 5 there is more reason for diagnosing hilum tubercle. It will be seen in these examples that the striæ tend to spread upwards and outwards, and are rather more extensive, and are more defined. Fig. 4 is a radiogram of a girl, aged 17, who was delicate and backward, and had had tuberculous glands of the neck; she has now spent two seasons in the Alps, undergoing a course of heliotherapy, with the result that she is now, as far as can be seen, a strong, healthy, well-developed girl. Fig. 5 is taken from a very similar case of a youth, aged 19, who has also, after two years in the mountains, completely regained physique and strength.

Figs. 6 and 7 are given as instances in which a radiogram will sometimes bring forward unsuspected lesions in the lung. Fig. 6 is a radiogram of a man, aged 30, in whom tuberculosis was suspected owing to loss of weight, fatigue, &c., but in whom nothing definite was ever made out. There has been, at any rate recently, no cough or sputum, no fever, and none of the classical signs and symptoms of pulmonary tubercle, except loss of weight and debility; physical signs are conspicuous by their absence, and yet it will be seen from the radiogram that there is a well-marked circular cavity at the apex of the left lung, which makes the diagnosis perfectly simple and straightforward, and permits of much more satisfactory advice than could be given without this knowledge. This patient is rapidly gaining strength and weight, and to all intents and purposes is now a perfectly normal man. Fig. 7 is a slightly different type of case, but none the less interesting. This patient has a very definite and easily detected lesion over the right upper lobe, probably of some two years' standing. A year ago he had a breakdown accompanied by hæmoptysis and fever, and was in bed for some weeks. He recovered, and since then has gone ahead rapidly; he has regained his health and strength, and except for a little morning sputum, which generally contains a few tubercle bacilli, has no inconvenience from the disease. The physical signs are the same as before—i.e., well-marked classical signs of old trouble over the right upper lobe. In spite of most careful examination, one is unable to elicit definite evidences of trouble elsewhere in the chest, but on radiographic examination it is seen that there is a well-marked cavity in the middle part of the right lung, and also a definite patch in the lower part of the left lung. These were not present previous to the breakdown a year ago, as seen by comparing radiograms taken then with the present one; and this information, again, is of great value in dealing with the case.

Fig. 8 is an example of scattered tuberculosis over the upper lobe of both lungs; in this case the disease is of the superficial type of fairly recent origin, and does not throw a very deep shadow. The older the foci and the more fibrotic they become the more dense are the shadows in the radiogram.

Fig. 9 shows this very well. Here is a case of some 15 years' standing, known to us from its start. There was a localised focus in the upper lobe of the left lung, which healed soundly after a year or two's treatment, and this patient has been working in London ever since without a breakdown. The localisation and extreme denseness of his old fibrotic patch are well seen in this radiogram.

Figs. 10 and 11 are given as an example of a pleural case, and the X ray appearances seen in such a type. This patient's history is that in the spring of 1922 he had an attack of pleurisy, with an accumulation of serous fluid. He was confined to bed for a considerable time, and became much emaciated and debilitated. Although tuberculosis was strongly suspected, it was never definitely determined. He was sent to Switzerland in June, 1922, and Fig. 10 shows the X ray appearance on arrival. Fig. 11 is a radiogram taken in November, 1922, and the striking difference is well seen.

Fig. 12 is a radiogram of a somewhat remarkable case, showing the extreme distortion which can be produced by the contracting of fibrous tissue. The patient is a man, aged 29, who acquired tuberculosis two years ago. The disease was situated over the middle portion of the left lung, and was of a very severe type. For a long time he was extremely ill, with much fever, and all the classical signs and symptoms of a breaking-down tuberculous focus; there were also recurring attacks of pleurisy in the neighbourhood of this lesion. However, the patient turned the corner, the whole thing settled down, and fibrosis set in. We have now had the opportunity of observing this patient for over a year, and have, with great interest, watched the effect of the contraction of the fibrous tissue. It will be seen that the heart and the mediastinum have been displaced considerably towards the left; the heart has also been pulled up into a horizontal position, the spleen is left uncovered; and the vertebræ are seen very plainly in the centre of the radiogram. We may add that this patient's general condition is exceedingly good, although, of course, he is somewhat short of breath on exertion, owing to the hampered and fixed state of his heart.

Fig. 13 is a case of scattered tuberculosis in both lungs, in a man, aged 28, which has undergone a healing and fibrotic change. There is well seen an adhesion of the diaphragm, pulling it up in one place into a little spike; a fibrous band, marked with an arrow on the radiogram, is also well shown. This case is also interesting as it shows the presence of an oval cavity, on the right side, quite undiscoverable by ordinary clinical methods.

Fig. 14 is taken from a lady, 24 years old, who recently had an attack of dry pleurisy at the base of the right lung. There is no evidence of tuberculous disease, either by clinical or X ray examination, in any part of the lungs, although the most careful investigations have been made. There is no cough, sputum, fever, or any other symptom, but the effect of the pleurisy upon the right diaphragm is clearly seen. On radioscopy the diaphragm is seen to be almost straight, the diaphragmatic angle has disappeared, and the diaphragm itself is fixed, does not move on respiration, and is considerably higher than normal. This appearance is also seen in the radiogram.

Summary.

The following are some of the more important conclusions to which we have come regarding the question of X ray examination of the chest.

1. An inexpert opinion on a radiogram is valueless and often misleading.
2. A good radiogram of a normal chest shows distinct mottling and hilum shadows which need not be referable to tuberculosis.
3. A radiogram may sometimes demonstrate much more extensive disease than physical signs reveal, and may sometimes be the sole means by which a diagnosis can be made.
4. Radioscopy and radiography are essential before undertaking and during the continuance of artificial pneumothorax.

LONDON DERMATOLOGICAL SOCIETY.—A meeting of this society will be held at 4.30 P.M. on March 20th at St. John's Hospital, 49, Leicester-square, W.C. 2, when Dr. Robert Craik will communicate Some Observations on the Pathogenic Yeasts.

MORE SMALL-POX AND PRECAUTIONS.—A fresh case of small-pox was reported at Nelson, Lancashire, on March 5th. This patient had been in direct relation with members of a local institute and members of a football team a fortnight ago. On the following day three fresh cases—school-children—were notified. The children live in different parts of the town and do not attend the same school. In one other case in a man, making five new cases in a fortnight, is reported. Nelson has a large number of unvaccinated inhabitants; during the week ending on the 5th no less than 600 persons were vaccinated, whilst 16 cases were reported to be in the Taplow Isolation Hospital. One case has been admitted to the Ainsworth Isolation Hospital at Radcliffe.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ORTHOPÆDICS.

A MEETING of this section was held on March 6th, Mr. T. H. OPENSHAW, the President, being in the chair.

Mr. A. S. BLUNDELL BANKART introduced a discussion upon the

TREATMENT OF SPASTIC PARALYSIS.

This was due, he said, in the majority of cases to a defect of the upper motor neurone. The defect of the neurone being incurable, surgical treatment was limited to the relief of mechanical or functional disabilities. The cases were chiefly the cerebral palsies of children, diplegias, hemiplegias, paraplegias, and less often monoplegias showing the contractures resulting from the spastic condition of the muscles—in the lower limb typically spastic equinus with flexion of the knee and adduction of the thigh, and in the upper limb flexion of the forearm and wrist and pronation. The degree of mental impairment associated with the spasticity was a factor of great prognostic importance; it would be obviously unwise to operate upon idiots, and operation was also contraindicated in cases of progressive disease. Physiologically, spastic contracture was a tonic reflex contraction of muscles, a spinal reflex uncontrolled by the higher centres, dependent upon the integrity of the reflex arc. Permanent change in the contracted muscle, anatomical shortening, might be long delayed but inevitably occurred, and, when present, must be treated by stretching the muscle or lengthening or dividing its tendon. Purely physiological contracture might be attacked either on the afferent or on the efferent side of the reflex arc. Foerster had advocated attack upon the afferent side by division of a number of posterior nerve roots, but this operation had given disappointing results and was now rarely performed by orthopædic surgeons. Attack upon the efferent side might be upon the motor nerve, as advocated by Stoffel, or upon the muscle itself either by diminishing its range of action by stretching it, or by tendon lengthening, or by tendon transplantation. The latter method had long been in use; it involved tenotomies or open lengthening or division of muscles, the adductors, the hamstrings, and the tendo Achillis, prolonged splintage in the corrected position, and the use, in many cases, of walking instruments. In spite of all these precautions relapse not infrequently occurred. The principle of Stoffel's operation was the destruction of a suitable proportion of the muscle fibres in the spastic muscle by cutting out their nerve-supply, thus allowing the deformity to be overcome by the action of the opposing non-spastic muscles, while still leaving some power in the affected muscle or group of muscles. Thus, for adductor contracture of the thigh one or both divisions of the obturator nerve were resected; for flexion contracture of the knee the nerve tracts to the long head of the biceps, the semimembranosus, and part or the whole of the semitendinosus were divided; while for equinus contracture one-half or two-thirds of the tract to the gastrocnemius and soleus were resected. Similar operations upon the nerve tracts to the pronators and flexors of the forearm were performed for contracture of those muscles. Stoffel developed the "cable theory" of nerves upon which the success of these operations depended, and showed that the cross section anatomy of the tracts in a large nerve trunk was fairly constant in any given situation. From a knowledge of the position of the tracts it was possible to divide any proportion of the tract that might be desirable in an individual case. The main nerve trunk being easily exposed, Stoffel's operation was both more simple and more adaptable than any other yet devised. The effect on the spastic muscle was immediate and lasting, and the necessity for prolonged after-treatment was abolished. The end-results were most satisfactory in the case of the lower limb, children quite unable to stand being enabled to walk although the gait was ungainly, while in the less severe cases the improvement was often striking. In the case of the upper limb the natural tendency of the child to use the unaffected arm often led to neglect to make use of the improved function possible in the affected arm after operation; the flexion and pronation deformity was, however, abolished, and this alone was a satisfactory achievement.

Discussion.

The PRESIDENT had operated on nearly 100 cases of spastic paralysis by the older methods of tendon and muscle section which he had found on the whole satisfactory, especially if enough tendon were exsected. He had no personal experience of Stoffel's operation and only a limited experience of Foerster's operation, in which it was difficult to find the right roots and which yielded results certainly no better than those of the older method.

Dr. GEORGE RIDDOCH had been impressed by the results of Mr. Bankart's operations. He would have liked to have heard more of the methods of preventing contractures in spinal cord lesions, and pointed out that in such lesions there was a period of flaccid paralysis before the spasticity came on; during the former period treatment by splintage, &c., should be instituted to prevent the occurrence of contractures during the latter period. When the reflex arc was being restored very slight stimuli resulted in spasm and must therefore be avoided.

Mr. MUIRHEAD LITTLE said that his experience and his practice had been very similar to those of the President, and while he had no personal experience of the method advocated by Mr. Bankart, he welcomed his paper as a valuable contribution to our knowledge and a distinct advance, if not an ideal method. As regards Foerster's operation, that gentleman laid down as a rule that rhizotomy was only advisable in cases of severe spasm and good intelligence, a combination which was very rare indeed. Mr. Little had, however, had one such case in which he divided posterior nerve roots. As a result the spasm disappeared, but the child had scarcely any powers of balance and could hardly walk alone when last seen.

Mr. E. LAMING EVANS pointed out that both Hoffa and Lorenz had performed such operations before Stoffel described the operation now known by his name. While he would not go so far as Mr. Bankart in condemning the older operations of tendon section, &c., he agreed that Stoffel's operation gave admirable results in certain cases, notably in pronator spasm and adductor spasm in the thigh. He had noticed that the operation of muscle section of the adductors gave better results in some cases than in others, and suggested that the better cases were those in which the obturator nerve had been unintentionally divided. For contracture of the hamstrings he preferred the older operation, and for spastic equinus advocated open lengthening of the tendo Achillis which would not result in calcaneus deformity if care were taken to keep the knee extended.

Mr. H. A. T. FAIRBANK pleaded for the selection of an operation to suit each case individually, and discussed the age at which operation should be performed; in the case of the leg he operated at 3 years if the child could walk, but in the case of the arm preferred to wait until 6 years or later in order to secure the child's intelligent coöperation in after-treatment. He advocated the nerve operation for knee flexion (combined, where necessary, with tendon lengthening), but for valgus deformity had been disappointed with the results of section of individual nerve branches to the peronei. Where both branches of the obturator nerve required section he preferred the extraperitoneal abdominal operation. In cases where Stoffel's operation had been performed on the anterior tibial nerve the results had been bad; but the result of this operation for internal rotation of the thigh had been very satisfactory in one case. In the arm he thought the resulting paralysis outbalanced the good effects of a nerve operation, and in the case of spasm of the flexor carpi ulnaris would prefer a tendon transplantation. He did not agree as to the non-necessity of after-treatment by splints, &c., after Stoffel's operation. Foerster's operation had a high mortality without giving any improved results.

Mr. A. ROCYN-JONES was pleased with Stoffel's operation where the lower limb was affected, but preferred tendon transplantation in the upper limb. Really good results could only be obtained by any operation in cases where the spasm was not severe.

Mr. W. T. G. PUGH referred to a recent paper by Sharp, of New York, who divided cases of spastic paralysis in children into two classes: (*a*) Those in which there were symptoms and signs (ophthalmoscopic and from lumbar puncture) of increased intracranial pressure; and (*b*) those in which there were no such signs. For the former class he had performed decompression operations on the skull with results which were claimed to be good in a certain proportion of cases.

Mr. W. ROWLEY BRISTOW pointed out that section of both divisions of the obturator nerve would not throw out of action the main adductor—adductor magnus—so that it was of relatively small importance whether one or both divisions were cut. For spastic equinus he had found the older methods very satisfactory, but Stoffel's operation gave the best results in adductor spasm. The tendency in performing Stoffel's operation, at least in the first few cases, was to do an insufficient nerve section, but this was merely a matter of accurate "working out" beforehand. He agreed with Mr. Fairbank that one should adopt the operation best suited to the individual case.

Dr. A. FEILING was glad to hear Foerster's operation so generally condemned, and thought there was a field for Stoffel's operation outside the cerebral palsies of children. Mr. Bankart had operated for him on an elderly lady bedridden with paraplegia in flexion due to disseminated sclerosis. Stoffel's operation upon the nerves to the hamstrings and calf gave a satisfactory result, the patient being enabled to get about. But extensor spasm subsequently developed in one foot, which pointed the moral that one should be certain before operation that the lesion was not a progressive one. He did not think the operation was of much use in the arm in cases of hemiplegia.

Mr. R. C. ELMSLIE pointed out the necessity for accurate diagnosis before operating, having operated, naturally without benefit, upon two cases of congenital syphilis. Since then he had had the W.R. performed upon all cases. He thought it would be a mistake to scrap the old operation, especially in the case of the calf muscles, on account of the difficulty of judging the proportion of the nerve to exsect. He asked whether flexion at the hip and knee were not interrelated and what could be done for contracture of the psoas. He advocated re-education after Stoffel's operation.

Mr. NAUGHTON DUNN had more experience of operation upon muscle than on nerve in these cases, and thought that operation should be devised to suit each case. Spasm was seldom limited to one set of muscles, so that some form of splintage was usually necessary after any operation. If there was power in the non-spastic muscles he would prefer an operation upon muscle. He had tried Stoffel's operation, crushing and not cutting the nerve for peroneal spasm, and had been pleased with the results on the whole, although a few cases relapsed, owing, he thought, to insufficient nerve section.

Mr. P. JENNER VERRALL had had good results from Stoffel's operation in the legs of spastic children, but not in the arms of adults. He had successfully treated flexion at the hip by section of the psoas at its insertion, leaving the iliacus intact.

The PRESIDENT had always performed subcutaneous tenotomy of the tendo Achillis with only one exception in which the wound suppurated. For limitation of supination he divided the pronator radii teres and for limitation of external rotation of the upper arm he cut the insertion of the subscapularis. He had had cases where, in spite of having got the legs straight by tenotomies, the patient was still unable to walk owing to flexion of the trunk by the psoas, section of which muscle brought a successful result.

Reply.

Mr. **Bankart**, in reply, said that cases of paraplegia in flexion were always severe and difficult to treat. Dr. Riddoch was talking of recoverable lesions, while the speaker had devoted his paper to permanent conditions in which contracture would recur after the most prolonged splintage as soon as the splints were removed. He agreed that Stoffel was not the first to perform the operation he advocated, but argued that it was the best operation yet devised for physiological contracture. When there was anatomical shortening the muscle must be attacked directly, and he sometimes combined this measure with the nerve section. He agreed that in the actual section of nerve there was a tendency to do too little rather than too much. He divided both divisions of the obturator nerve in the thigh and personally was disinclined to perform the abdominal operation. There were no age-limits for the operation, but he rarely saw cases younger than 2 or 3 years of age. The true Stoffel operation was carried out upon the main nerve trunk and not upon nerve branches. Personally, he had not been troubled by hip flexion; he began by operating for the spasm of the calf muscles and rarely had to treat even the hamstrings and never the hip flexion. While he agreed that some after-treatment might be beneficial, he said that there was no necessity, after Stoffel's operation, for cumbersome walking instruments.

SECTION OF NEUROLOGY.

A meeting of this section was held on March 8th, with Dr. **Wilfred Harris**, the President, in the chair.

Dr. **E. Farquhar Buzzard** opened a discussion on

THE TREATMENT OF NEURO-SYPHILIS.

He reminded the section that the previous Sunday was the 430th anniversary of the return of Columbus from his voyage of discovery of America. The incidence in these islands of the disease (syphilis) brought back from America fell first upon Aberdeen and then upon Edinburgh; both these cities had met their responsibilities in fighting the scourge by adding many recruits to the ranks of the medical profession. In order to provoke discussion Dr. Buzzard laid down the following principles: (1) No distinction could be made between interstitial and parenchymatous neuro-syphilis as regards their preventive or curative treatment, since both were evidences of active syphilitic processes due to the presence of the spirochæte in the nervous system; (2) prevention of neuro-syphilis depended upon the complete eradication of the spirochæte or continued abeyance of its activities; and (3) that since there were no reliable data upon which cure (or eradication of the spirochæte) could be based, patients with syphilis should continue intermittent treatment for the rest of their lives.

Parenchymatous Neuro-syphilis.—It was formerly held that while the interstitial variety of cerebrospinal syphilis was due to the active virus, the parenchymatous forms were due to some mysterious aftereffect of the disease (or even, it was suggested, to the effects of treatment). The discovery of the spirochæte in the central nervous system in cases of tabes and general paralysis resulted in the view that these diseases were the result of active syphilisation of the nervous tissue, so that the same principles should govern their preventive and curative treatment as were applied to the treatment of syphilis elsewhere. In other words, the appearance of neuro-syphilis must be considered as evidence of failure to cure the primary disease. Yet in spite of the fact that various metals besides mercury were now available for treatment the late manifestations of syphilis were still frequent. He submitted that better results would not be obtained until we admitted that the word "cure" could not justifiably be used in relation to syphilis, and until we supported the principle of lifelong treatment.

Value of the Wassermann Reaction.—Dr. Buzzard then quoted from a recent standard text-book, in which it was stated that many cases were "cured by a comparatively short course of arsenobenzol treatment," as judged by the "persistence of a negative W.R. for some years afterwards and the propagation of healthy children." He submitted that neither was evidence of cure, and that many tabetics and general paralytics could pass such a test. As regards the W.R. he held that while a positive result was a valuable piece of confirmatory evidence, a negative result was absolutely valueless; yet a negative result was highly credited and so became a direct menace to proper treatment.

Need of Continuity of Treatment.—While it was not yet proved that periodic courses of treatment year after year would prevent the development of neurosyphilis, there was evidence that the more thorough and prolonged the treatment the less likely and the more delayed were the cerebral and spinal complications. Thus Fournier tabulated 321 cases of tabes according to treatment; in 24 there was no treatment of the original disease, in 70 treatment was insufficient, in 108 treatment with mercury lasted 3 to 6 months, in 74 similar treatment for 6 to 12 months, in 32 for 1 to 2 years, and in only 13 cases for a period of 2 to 4 years. The response of vascular and meningeal lesions to antisyphilitic measures had long been recognised, and he personally was convinced of the value of the same measures in cases of tabes, and perhaps of general paralysis when treatment was sufficiently early and prolonged. It was, of course, impossible to do away with such physical signs as Argyll Robertson pupils and absent tendon jerks; the result was satisfactory if the disease could be arrested and the disorders of function improved or cured by re-educative methods. Dr. Buzzard employed both mercury and arsenic in the treatment of neuro-syphilis. He did not favour the intrathecal method of administration of the latter, since it had not, in his experience, yielded any better results than those of intravenous or intramuscular medication, and its repeated use was attended by much discomfort and some danger to the patient. While he disregarded the Wassermann reaction in the blood he considered occasional cytological examination of the cerebro-spinal fluid helpful in regulating the treatment of acute conditions.

Contra-indications to Antisyphilitic Treatment.—Great caution was required in the treatment of patients showing advanced cardio-vascular disease. Albuminuria, without renal inefficiency, often cleared up under treatment, but true renal inefficiency was a contra-indication. Lately he had seen patients with early optic atrophy derive much benefit from energetic treatment which he had formerly considered to be contra-indicated in this condition. Leslie Paton had recently supplied information suggesting why some forms of optic atrophy were more amenable to treatment than others.

The Clinical and Biological Aspects of Syphilis.

Dr. **H. MacCormac** said that syphilis was studied from two different standpoints; either the signs and symptoms were observed, or such biological reactions as the W.R. The former was concerned with the anatomical structure involved, the latter indicated infection with the spirochæte. When considered from the latter point of view syphilis was divisible into two groups of cases, early cases in which the symptoms and signs rapidly disappeared and the W.R. became negative under treatment, and late cases in which the W.R. remained positive in spite of treatment. The speaker's routine treatment for the first group was the intravenous injection of a "914" compound once a week for 10 weeks, followed by 12 intramuscular injections of mercury at weekly intervals. If the W.R. was then negative, mercurial treatment was continued for two years, but if positive the course of " 914 " was repeated. In some cases where patients had discontinued treatment early, cure had, as judged by a negative W.R. and the propagation of healthy children, apparently been brought about by a few injections of " 914." He regarded the persistence of a positive W.R. in late syphilis as indicating that cure could not be hoped for or expected, so that treatment was directed solely to the local lesion. For such cases he employed short intensive courses of treatment, repeated as circumstances dictated. Between these two groups was an intermediate series of cases, including those patients whose early treatment had been insufficient and whose W.R. was found to be positive two or three years later. For this class, some of whom showed early involvement of the central nervous system, he thought prolonged treatment justifiable in the hope of obtaining eventual cure.

Neuro-syphilis not due to a Special Spirochæte.

The belief that neuro-syphilis might be due to a special variety of spirochæte arose from the common observation that when late lesions appeared in the skin the nervous system escaped, and vice versa. Dr. MacCormac had seen gummata in conjunction with neuro-syphilis on two occasions, and further pointed out the frequency of tongue manifestations in all forms of late syphilis. Fournier pointed out that in cases of general paralysis the primary lesion was often transient, and secondary eruptions ephemeral or non-existent. While many patients with neuro-syphilis denied all knowledge of infection, the same occurred with cases of late cutaneous lesions. There was thus no positive evidence of the existence of a neurotrophic spirochæte and no indication for modification of treatment to meet the possibility of a special infection.

Changes in the cerebro-spinal fluid in syphilis had been discovered by Wechselbaum, and the actual invasion of the cerebro-spinal fluid by the spirochæte at an early stage had been demonstrated by Plant and others. Some authorities placed the frequency of these changes at as high a figure as 80 per cent.; it was certainly far higher than the rate of incidence of neuro-syphilis. Further, the work of Fildes, Parnell and Maitland was quoted to show that the W.R. of the cerebro-spinal fluid was generally influenced by treatment with even small doses of " 914." One must therefore agree that it was possible to affect the central nervous system by the ordinary intravenous method of medication at least in the early stages of the disease. Late syphilis of the nervous system was as resistant to treatment as late syphilis elsewhere, but in the interstitial form, at least, derived maximum benefit from intensive intravenous medication. In corroboration of this it was pointed out that interstitial disease in a structure totally devoid of blood-vessels, the cornea, was favourably affected by intravenous injections. Dr. MacCormac thought that no advantage was to be gained by spinal drainage or by intrathecal medication, and believed that the apparent success of the latter in some cases where intravenous therapy had apparently failed was due to the delay, often of two or three months, in appearance of the good effect of the intravenous form of therapy.

The Needs of the Individual Case.

Sir **JAMES PURVES-STEWART** had no regular treatment for syphilis, but adapted his treatment to the needs of the individual case, with the proviso that treatment of the disease itself should be lifelong. In the case of neuro-syphilis the method of intracisternal injection of salvarsanised serum, which he had already described at the British Medical Association conference in Glasgow, was meant to be supplementary to and not to replace the ordinary methods of treatment. By the employment of this method he had secured a very good result in one case of early neuro-syphilis exhibiting Jacksonian fits in the right arm. The fits stopped after one intra-cisternal injection, and the man was well one year later. In addition the W.R. in both blood and cerebro-spinal fluid had been made negative and the cell content of the latter had shown a steady decline almost to normal. This was an exceptionally good result; other cases had improved to a less extent. In general paralysis he had found it impossible to get the W.R. in the cerebro-spinal fluid negative, although some cases had benefited. The technique was quite simple; a needle passed through the atlanto-occipital ligament would be felt to enter the cisterna magna at a point where it (the cisterna) was three-quarters of an inch wide, so that with reasonable care there was no danger of injuring the medulla.

Colonel **L. W. HARRISON** said that the older he became the more prolonged was the treatment he advocated for syphilis. Even general paralysis could be benefited by antisyphilitic treatment. While agreeing that a negative W.R. did not necessarily indicate cure he advocated the performance of the W.R. in the cerebro-spinal fluid of all cases of syphilis within five years of infection, as experience showed that this was the latest period at which the W.R. could be affected by treatment. He mentioned the frequency of the occurrence of aneurysms amongst tabetics as further evidence against the theory of a special spirochæte for neuro-syphilis. Judging from recent experience with silver salvarsan he thought that the dangers of arsenobenzol medication in cases of cardio-vascular disease had been much exaggerated, and he added that these preparations (arsenobenzol) were useful adjuncts to mercury in the treatment of late syphilis. He had seen some good results from intrathecal medication in tabes, but had also seen equally good results from simple lumbar puncture.

Dr. **H. HEAD** pointed out that a whole group of diseases was included under the title of general paralysis, and that these cases showed every gradation between two extremes as regards the effects of treatment. There were some in which the cerebro-spinal cell content fell rapidly and the W.R. became negative under treatment within six months, and others who showed little or no improvement either in symptoms or biological reactions. There was nothing to show to which class any given case belonged except time and the effects of treatment. He pointed out that the mercury in mercurialised serum used for intrathecal injection was converted into an inert albuminate, and suggested that the reaction following an intrathecal injection was one of protein shock.

Dr. **G. RIDDOCH** considered that treatment should be directed against the primary disease, and should be continued until the W.R. in both blood and cerebro-spinal fluid was negative, or until the persistence of a positive reaction and a high cell content of the cerebro-spinal fluid made it obvious that no further treatment would benefit the disease, when treatment should be directed to symptoms.

The Risk of Toxic Effects.

Dr. **C. P. SYMONDS** pointed out the risk of toxic effects from such dosage of arsenobenzol compounds as were employed by some of the speakers. In his own practice he now divided the total dose of 10 g. of arsenobenzol into two courses with an interval between, on account of the high incidence-rate of toxic phenomena when the dose was given in one series. He had seen cases of tabes with a negative W.R. both in blood and cerebro-spinal fluid. It was difficult to assess the results of treatment of neuro-syphilis, since cases were apt to show spontaneous remissions and aggravations of symptoms.

Dr. **A. FEILING** agreed with the opener that a negative W.R. in no way indicated cure of the disease, and gave instances of cases of indubitable neuro-syphilis with negative reactions. He had seen severe toxic phenomena, such as acute myelitis, coma and paralysis, from excessive zeal with arsenobenzol.

The **PRESIDENT** was glad to have heard the note of warning by the last speakers. In his experience the biological reactions were not helpful in neuro-syphilis. He preferred the original salvarsan (or kharsivan) to the newer "914" compounds, and gave instances where he had used "606" with success after "914" had failed, although he now only gave two injections. He had found that the intrathecal injection of salvarsanised serum collected 14 days after the intravenous injection had a wonderful result upon the pains of tabes; after a transient aggravation for a few hours they disappeared completely, often for a year. He was at present giving a trial to the pyrexial treatment of general paralysis with results which, so far, were very satisfactory.

Dr. **Buzzard**, in reply, said he could not agree with Dr. MacCormac's view of the W.R., but agreed that there was not sufficient evidence of a special spirochæte for neuro-syphilis. His frank declaration to patients that there should be no end to the treatment of syphilis had never produced any psychic ill-effects. He was not convinced that Sir J. Purves-Stewart's intra-cisternal medication had achieved any more than might have been done by intravenous injections. He gave a further instance of neuro-syphilis with a W.R. which remained negative after a provocative injection.

Dr. **MacCormac**, in reply, said he had not had any unusual proportion of toxic effects from the course of arsenobenzol he employed. He agreed that the W.R. was not generally helpful in neuro-syphilis, but maintained that a negative W.R. three years after infection was a fair criterion of cure. All his cases of neuro-syphilis were told to report from time to time for short courses of treatment.

MEDICAL SOCIETY OF LONDON.

Value of Laboratory Tests in Diseases of the Liver and Pancreas.

A meeting of this Society was held on March 11th, Lord **Dawson**, the President, being in the chair, when Dr. **Langdon Brown** read a paper on this subject.

He said that the liver and pancreas were both developed as outgrowths from the elementary tract, and their close coöperation was shown by the way they both poured their secretions into the intestines at the same point, and in their complementary rôles in the utilisation of fat and in carbohydrate metabolism. The liver helped to prepare all three foodstuffs for utilisation by the tissues. The bile was an excretion and a secretion, and the liver was an important agent in detoxication and in maintaining the constant composition of the blood. The liver had a great reserve capacity and did not reveal its failure of function to ordinary tests until the time for successful treatment was past. Its various functions were not equally inhibited by disease, so that tests covering different fields of liver activity must be applied.

Tests of Hepatic Metabolism.

(*a*) *Protein.*—The nitrogen partition test aimed at estimating hepatic inefficiency in respect of protein metabolism by determining any loss of the disaminating and urea-forming functions of the liver. One would expect that in hepatic inefficiency urea excretion would fall, while the excretion of the precursors of urea, such as ammonia and amino-acids, would not. But in practice it was found that a small proportion of the liver substance was capable of making the normal amount of urea; the amount of urea excreted varied with the diet; increase in ammonia formation might be a protective step against acidosis and was not evidence of failure of urea formation; and lastly, variations in the kidney threshold might materially affect nitrogenous excretion. This difficulty could be surmounted by an examination of the blood rather than of the urine, but the other three objections, Dr. Langdon Brown thought, vitiated the nitrogen partition test. Also de Wesselow and Wyatt had shown that in normal pregnancy a low urea excretion was the rule, so much so that a rise of blood-urea above 40 mg. per cent. implied a failure of renal function in pregnancy. This added to the difficulty of applying nitrogen partition tests to the hepatic toxæmias of this condition.

(*b*) *Carbohydrates.*—"Lævulose test." Lævulose could, within its limits of tolerance, be stored by the liver and muscles as fast as it entered the blood-stream. Maclean and de Wesselow[1] showed that this sugar when administered by mouth in doses of 30 to 50 g. in healthy subjects with an intact liver did not raise the blood-sugar, but when the liver was defective, the sugar was not stored quickly enough and entering the blood-stream increased the blood-sugar in proportion to the hepatic defect. The speaker considered this levulose test to be one of the best for hepatic efficiency. According to Spence this test showed that in catarrhal jaundice some hepatitis was present and by its means Mackenzie Wallis had shown that where a course of an arsenical preparation (such as salvarsan) had been given, some hepatic deficiency existed for at least three months.

Diastase Test.—This was originally defined by Wohlgemuth as a renal efficiency test. He estimated the amount of diastase in the urine, and claimed that if renal efficiency were impaired, the output of diastase would fall. Dr. Langdon Brown and Dr. Mackenzie Wallis had worked on cases of war nephritis, but their more recent work had shown that the diastase in the urine did not necessarily run parallel with the diastase in the blood. This test had proved of more value in recognising pancreatic disease because the alteration of the amount in the blood was so gross. However, in very chronic conditions there might be no excess, but a deficiency. This was so in ordinary clinical diabetes. Cammidge, with Forsyth and Howard,[2] had adduced reasons for believing that diastase was hepatic in origin, since the diastase value increased as more and more of an animal's pancreas was excised, right up to total extirpation, while hydrazine phosphate, which was a liver poison, but was not toxic to the pancreas, reduced and might completely abolish the diastase output. They concluded that diastase was the agent which converted glycogen into sugar, and its action was controlled by the internal secretion of the pancreas. If this control failed there would be increased diastase production by the liver, and increased diastase output would suggest pancreatic insufficiency, but a defect of diastase in the blood had not helped much in determining hepatic insufficiency, and defective output in the urine could not help much because of the behaviour of the threshold of the kidney.

(*c*) *Fats.*—Leathes had shown that the fat normally present in the liver was the unsaturated one, but the one that occurred after poisoning with phosphorus or after an anæsthetic was the saturated one. He considered that the function of the liver was the conversion of saturated fats into unsaturated ones. Whipple devised the lipase test. Normal blood contained a very constant amount of fat-splitting ferment which was increased in diseases of the liver, so that the increase of lipase in the blood as measured by the power of splitting ethyl butyrate, was a criterion of hepatic damage. Whipple had applied this to chloroform poisoning, and Mackenzie Wallis[3] to salvarsan poisoning. The damage had, however, to be rather gross before the lipase increase was enough to be reliable.

Tests of Antitoxic Function.

The process of rendering a poison harmless by conjugating it with a protective substance was most often carried out by the liver. Thus the toxic indol was combined with sulphuric acid into the harmless sulphate indican, but if the liver cells were diseased such combination could not take place, so that such substances as indol, skatol, and phenol could pass directly into the blood. There was no simple test for recognising this. The formation of harmless glycuronates after administration of camphor, morphia, &c., was a liver function. A simple test was introduced by Roch, who gave ½ gr. of sodium salicylate half an hour before food. This should be converted into a glycuronate which did not give a purple coloration with ferric chloride solution. If the urine excreted for four hours after a meal did give this colour, hepatic insufficiency was present.

[3] Medical Research Council's Report on Salvarsan, vol. ii.

The Hæmoclastic crisis might also be regarded as due to a failure of the antitoxic power of the liver. Widal[4] considered that when the liver was diseased the normal post-prandial leucocytosis was replaced by a leucopenia. C. M. Wilson considered that this was the only test which gave an early warning of hepatic insufficiency.

Tests of Biliary Function.

The gall-bladder concentrated the bile and added cholesterol and mucin, so that examination of the bile secreted into the duodenum would reveal the presence or absence of obstruction to the cystic duct. H. E. Griffiths[5] had confirmed the general impression that gall-stones produced reflex hyperchlorhydria in 90 per cent. of cases. A sharp flow of bile into the duodenum, which could be extracted by the Einhorn tube, was promoted by the injection of a few drachms of concentrated magnesium sulphate solution provided the bile passages were patent. This test had enabled him to diagnose empyema of the gall-bladder, which was confirmed at operation. Lyon[6] had extended this method by collecting three samples of bile, the first transparent and golden-yellow from the common duct, the second darker and more viscid from the gall-bladder, and the third thinner from the hepatic ducts. By examination of these three he was able to locate the situation of biliary disease. Failure of the bile to enter the bowel was indicated by steatorrhœa and increased intestinal putrefaction, with increase of indican in the urine. In incomplete obstruction of the bile-ducts the fatty contents of the stools might mask the colour due to small amounts of bile, but the presence of urobilin could still be demonstrated by spectroscopic examination of alcoholic extract of the fæces. Van den Bergh's test had been investigated by Dr. Christopher Andrewes, who concluded that "practically all cases were compatible with the theory that the direct reaction is due to obstruction and the indirect reaction due to disordered function of liver cells." The biphasic reaction limited the clinical value of the test; further, the test was gross and not likely to give help in other than cases easily diagnosable clinically. Dr. Langdon Brown went on to discuss the fate of the bile pigment, and stated his belief that urobilin was formed in the intestine from bile pigment through bacterial agency. As regards the presence of bile salts in the urine, in the early stages of jaundice this suggested an obstruction rather than toxæmic jaundice.

Tests for Pancreatic Inadequacy.

Signs of Defective External Secretion.—There might be failure of tryptic digestion, as shown by the presence of unaltered muscle nuclei in fæces after a meat meal, but this was not easy to prove. There might also be failure of starch digestion, and starch granules might be detected in the stools after unboiled starch had been given, but the most valuable test was the failure of fat digestion as shown by the presence of excess of neutral unsplit fat.

Signs of Defective Internal Secretion.—Diminished sugar tolerance might be expressed in glycosuria and hyperglycæmia two hours after a dose of 50–100 g. of dextrose, whereas the normal tolerance for dextrose was 150–200 g. The diastase test had already been discussed. Dr. Langdon Brown considered it one of the best for recent pancreatic damage. The adrenalin eye test of Loewi was simple and easy to apply. In the case of pancreatic insufficiency, the pupil dilated 20–60 minutes after dropping adrenalin into the eye. Normally this did not happen. Recently, however, the speaker had seen a positive reaction in the case of acute appendicitis.

Signs of Pancreatic Disintegration.—Pancreatic lipase could be found in the urine, and a pentose might sometimes be found in the urine from the breakdown of pancreatic nucleo-proteins. This was the basis of Cammidge's test. Dr. Langdon Brown felt that the ultimate diagnosis must rest on the clinical as well as the biochemical findings.

The Clinical Aspect.

Prof. F. Langmead said that he had endeavoured to use the tests under discussion in the clinical medical unit to assist in arriving at more accurate diagnosis. At the outset he was somewhat discouraged by the number of the tests and by the fact that it was only in the more acute cases that the tests were likely to be helpful, so that in such cases the patient was prone to die or recover before any considerable investigation had been undertaken. All research had a value, even though from a clinical aspect such value was not immediately obvious; but with the single exception of blood-sugar estimations in cases of suspected or true diabetes mellitus the laboratory tests had not seemed to him to have any practical usefulness in providing or establishing a diagnosis, amplifying prognosis, or directing treatment. With regard to the external secretory function of the pancreas little reliance could be placed on those tests in which the testing substance was submitted to all the vagaries of the alimentary canal. The diastase content of the urine, estimated with due regard to the pH value, was now losing rather than gaining adherents. The fat content of the stools, particularly the proportion of neutral and changed fats, was more helpful, but even this was often misleading, as in three cases (quoted by the speaker) in which the urinary diastase test also gave an equally incorrect indication of pancreatic disease, where, in fact, the post-mortem findings definitely proved there was none. Loewi's test had given him no help, but the internal secretion test by the reaction of the pancreas to a burden of sugar was of undoubted value. Of the liver tests, the hæmoclastic crisis test had little scientific basis, while the lævulose test, which appeared to be the most reliable, was applicable chiefly to acute destruction of the liver, and gave little help in chronic disorders such as cirrhosis. In short, he contended that efficiency tests for the liver, pancreas, and bile passages were still in their infancy, and had already outrun our knowledge of physiology. The difficulties of such tests were increased by the multiplicity and interdependence of the functions of the two organs. While he had no desire to belittle research, he saw a danger of these tests being used as ready reckoners of diagnosis, a function which they were as yet unfit to fulfil.

Dr. J. W. McNee agreed with Prof. Langmead that liver function tests were still in their infancy, and that it must necessarily be difficult to assess by any one test the function of an organ like the liver which had so many different activities. The lævulose test and the blood lipase test, for instance, were useful in acute but not in chronic liver disease. Tests involving the use of the Einhorn tube, and more particularly the dye tests, were of doubtful value. One simple test, that of Brewley, he had found useful; the small glancing fat droplets in blood seen under the microscope with dark-ground illumination were much diminished in chronic liver disease. The value of Van den Bergh's test lay chiefly in the fact that it re-directed our investigations to the blood where bile-pigments could be recognised in high concentration before they appeared at all in the urine. The biphasic reaction robbed this test of any real practical value, for it occurred in just those cases in which it might have been clinically helpful. Notwithstanding the fact that no one test afforded accurate information, a number of tests in conjunction might occasionally be helpful and by means of them he had recently saved two cases from the surgeon.

The Laboratory Side.

Dr. R. L. **MACKENZIE WALLIS** maintained that, while one test alone might be misleading, reliable and helpful results might be obtained from a combination of the tests. The lævulose-tolerance test was both accurate and delicate, and by the employment of this test he was able to show the damage done to the liver by salvarsan injections, and that the maximum damage occurred three months after the last injection. The disadvantage of this test was the lengthy and elaborate technique it involved; a simpler test given by 65 per cent. of these cases was the diphenylamine test in the urine. The lipase content of the serum was another test he had employed; fairly considerable damage had to be done to the liver before this test gave a positive result. He agreed with Dr. McNee as regards tests involving the use of the Einhorn tube, and suggested that the secretion of bile into the duodenum after the injection of magnesium sulphate was due merely to osmotic pressure. With H. E. Griffiths, he investigated the pancreatic function in cases of gall-stones, which subsequently came to operation so that the results had been checked. Hyperchlorhydria was present in many, the blood lipase increased in some, and the urinary diastase generally increased in these cases. By the employment of such a combination of tests he maintained that valuable help could be given to the clinician.

Dr. E. C. **DODDS** pointed out that recent experimental work showed that an animal could survive the excision of four-fifths of its liver substance, so that the normal liver possessed an enormous reserve. Similarly in the human subject it was well known that patients might have very extensive secondary growths in the liver without showing any signs of hepatic insufficiency. He considered that some help might be obtained from Fouchet's reaction in blood serum, which gave a brisk reaction in obstructive and a slower reaction in toxic jaundice; from the glycuronic-acid compounds reaction in urine (Roger's test); and from the rise of non-protein nitrogen compared with the amino-acid nitrogen of the blood.

Dr. G. A. **HARRISON** said that Loewi's adrenalin mydriasis test had been practically useless. Estimations of diastase in blood and urine had been valuable in acute and subacute pancreatic lesions, but generally of little help in chronic disease. A high urinary index, when accompanied by a raised blood diastase, was diagnostic of active pancreatic disease, but when accompanied by a normal value for blood was merely suggestive. [Here a slide was shown illustrating the various stages in the digestion of meat fibres which may be seen microscopically in a simple saline emulsion of fæces. It was concluded that, in the absence of gross diarrhœa, meat fibres showing well-marked transverse striations and irregular ends were very suggestive of pancreatic disease.] An important point in liver disease, Dr. Harrison continued, was the frequency of coincident damage to the pancreas, so much so that in many instances it was a good rule to test the efficiency of both organs. The difficulty was to devise methods that would test the one organ to the exclusion of the other. This criticism, for instance, applied to the new lævulose test, which otherwise had been valuable. Van den Bergh's reaction, coupled in severe jaundice with examination of the fæces for stercobilin and examination of the urine for urobilin, combined with a blood count, had often been instructive. Four illustrative cases were cited, and the conclusion was drawn that laboratory tests were of real value if regarded as an extension of the clinical examination and not in its stead.

A Surgical Point of View.

Mr. H. E. **GRIFFITHS** had already, in a Hunterian lecture,[1] endeavoured to show the intimate anatomical and physiological relationships between the stomach, pancreas, gall-bladder, and duodenum, which together formed a complex. Chemical tests would necessarily refer to the whole complex, although they might indicate greater change in one unit of the complex than in another. Laboratory tests, conducted by an expert, were, however, of the utmost value in research in confirming and interpreting clinical findings and in guiding the clinical worker in his search for further signs of disease. In his own work the tests conducted by Dr. Mackenzie Wallis had been most helpful. As an example of the value of laboratory tests in diagnosis and prognosis, he mentioned the fact that the presence of occult blood in the fæces in a case of carcinoma of the pancreas indicated that the growth was one of the more highly malignant columnar-celled adeno-carcinomas of the ampulla of Vater and not the less malignant spheroidal-celled carcinoma. He also maintained that the Einhorn tube was a valuable aid by yielding some of the duodenal contents for examination, and pointed out that the action of magnesium sulphate solution in promoting a flow of bile could hardly be due to osmotic pressure, since the sphincter concerned could withstand a pressure of 700 mm. of water. Loewi's test he had found useful, and it was always positive in cases which had recovered from acute pancreatitis even years afterwards. In the differential diagnosis between acute pancreatitis and perforated gastric ulcer the diastase in urine test, which took but half an hour to perform, was almost diagnostic and might save the surgeon from increasing his difficulties by making an incision on the wrong side of the abdomen. The "pancreatic tripod" of tests, Loewi's test, the diastase test, and the tests for fat in the fæces were of considerable value to the clinician.

Dr. A. M. **DE FOSSEY** (Vichy), speaking in French, said that in France urobilin was regarded as giving a valuable urinary test of hepatic efficiency, and it was held that other tests upon the urine were not of much value. The nitrogen partition test in the blood was regarded as an important index of liver function.

LIVERPOOL MEDICAL INSTITUTION.

A MEETING of this Institution was held on March 1st, Prof. J. **HILL ABRAM**, the President, being in the chair.

Dr. **ARTHUR GEMMELL** read a note on

Menstruation and Pregnancy in Hodgkin's Disease.

He described a case of Hodgkin's disease commencing in the second month of the second pregnancy of a young married woman, aged 23, which came under notice in 1919. The diagnosis was established by pathological examination of one of the glands, and treatment with arsenic and extract of lymph gland with the application of X rays to the site of glandular enlargement, was commenced and continued throughout pregnancy. The labour and puerperium were normal. Under further treatment all traces of glandular involvement disappeared. A third pregnancy commenced in 1920 and the glands began to enlarge at the eighth week. The patient then contracted influenza and aborted. Treatment as before caused complete disappearance of the swellings in a few weeks. Her fourth gestation began in the spring of 1922 and the glands enlarged when she was about 18 weeks pregnant, but treatment as before kept the disease in check, and she had a normal labour and puerperium with a healthy living child. Little had been written on the relationship of Hodgkin's disease to menstruation and pregnancy. A collection was made of 57 cases in the female from the Liverpool hospitals and the literature. In 17 cases between puberty and the menopause whose menstrual history was obtained, 14 showing varying degrees of oligomenorrhœa of varying degrees even up to complete amenorrhœa, and three were unchanged. Of the ten definitely parous women, six dated the onset of their disease from a pregnancy. Twenty-five cases of the series (43·8 per cent.) had their onset in periods of physiological amenorrhœa.

Considering the above with the well-known fact that women are less liable to the disease than men, it was suggested that it is the ovarian hormone which confers this relative immunity on women, and that they only contract the disease when there is a hypo-function of the ovary as regards its internal secretion. This hypo-function might be true, as before puberty or after the menopause, or relative as during pregnancy. The corollary to this suggestion was that ovarian extract should be given in addition to the treatment already mentioned. Post-mortem notes on the genitalia were only available in four cases, and these supported this view. Notes on the labours and puerperia were only available in six cases. These showed that on the whole labours were normal with a tendency to post-partum hæmorrhage. But three of the patients died within three months of labour. No abortions were definitely attributable to the disease. It would appear that where early Hodgkin's disease and early pregnancy occur together the uterus should be emptied and the woman warned of the danger of future pregnancies.

---

[1] THE LANCET, 1923, i., 265.

Dr. Gemmell drew the following conclusions: (1) Possibly Hodgkin's disease occurs, in the female, when there is a hypo-function of the ovary; (2) diminution in the menstrual flow is a symptom of Hodgkin's disease; (3) where early Hodgkin's disease and early pregnancy occur together, the pregnancy should be terminated.

Dr. Wallace Jones read a note on a case of

Osteitis Deformans.

The case was that of a man who commenced four years ago with pain in legs and muscular weakness which was thought to follow a slight accident to the hip. There was no family history of similar disease. He had lost 2 inches in height and the size of his hat had increased from 6⅞ to 7¼. There was a hunch-back appearance with kyphosis and marked bowing of both tibiæ. The movements of both hip-joints were limited. The arteries were thickened.

Dr. Thurstan Holland exhibited a series of lantern-slides showing the condition of various bones, including the skull. These demonstrated the typical changes in the X ray appearances caused by the various degrees of the combined rarefying and proliferating osteitis.

Dr. Henry Cohen read a note on

Oxycephaly,

illustrated by photographs and radiograms of three cases which had come under his observation. He emphasised the pressure origin of the so-called "digital markings" by comparing them with the appearances seen in hydrocephalus and brain tumour. In addition to the usual eye-signs, congenital cataract was present in a case of scaphocephaly.

Dr. Norman Capon believed that the convolutional impressions were due to disordered bone development rather than to pressure. Somewhat similar impressions were found in craniotabes; and when they occurred in hydrocephalus it was to be expected that the small volume of liquid lying between the external surface of the brain and the internal surface of the cranial bones would nullify direct pressure as the cause.

Mr. Robert Kennon read a paper on

Appendicitis

as a possible epidemic disease. In support of this he urged that whereas the yearly mortality in the Liverpool Royal Infirmary for the past five years had averaged 6·2 per cent. for acute cases, a study of the monthly admissions showed more cases admitted from May to October, and whilst periods of six months may elapse without a death, on four occasions the monthly mortality reached 33 per cent. Cases admitted in 1921 were greater in number, of greater pathological virulence (abscess formation 56 per cent. against 33 per cent. in other years), and had a higher mortality, especially in the month of June. The delay prior to admission was five days, in each of the past four years—operation within four hours shortened the length of illness by ten days—except in 1921, when the gain was reduced to five days. The mortality curves and incidence curves of hospital and general practice bore no relation to influenza, but followed other streptococcal diseases such as rheumatic fever, erysipelas, and puerperal fever, less so scarlet fever. Liverpool has a lower death-rate from appendicitis than Manchester, Birmingham, and Leeds when the population was considered.

ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

A meeting of this Society was held on March 1st, Dr. Alexander Ogston, the President, in the chair.

Dr. James Lawson, Tor-na-Dee Sanatorium, demonstrated a case of

Cauterisation of Pleural Adhesions by Thoracoscopy,

with skiagrams. The patient suffered from pulmonary tuberculosis affecting practically the whole of the right lung. An artificial pneumothorax was induced on that side, but complete collapse of the lung was prevented by adhesions in the region of the upper lobe and of the diaphragm. The thoracoscope was inserted into the pneumothorax cavity in the sixth space in the scapular line and the adhesions inspected; the upper adhesion was found to be too extensive for cauterisation; the lower adhesion was divided by the cautery passed through another cannula inserted in the sixth space in the anterior axillary line, the action of the cautery being controlled by inspection through the thoracoscope. Local anæsthesia only was employed. Following this operation there was a considerable increase in the amount of collapse of the lung, though not so much as would have followed had it been possible to deal with the upper adhesion also. Dr. Lawson described briefly the difficulties of the operation, showed the patient, and demonstrated the instruments required, and skiagrams of the case.

A short discussion followed, in which Prof. Ashley Mackintosh, Mr. F. K. Smith, and the President took part.

Mr. Smith then read a paper, with lantern illustrations, on the

Treatment of Fractures by Parham's Bands,

in which he pointed out that any method which reduced the loss of working time in a fracture case was worthy of trial. He indicated the disadvantages of different methods of fixation by open operation, and stated that he had found the advantages of Parham's method to be, the ease of application, the comparatively small wound required, the small amount of manipulation necessary, and the better chance of aseptic healing. The cases most suitable were those of oblique and comminuted fractures. In transverse fractures, bands alone were unsuitable, and should be combined with Sherman's plates. Mr. Smith demonstrated the special instruments used, and showed a series of lantern slides of skiagrams of eight cases before and after operation.

In the subsequent discussion, Prof. John Marnoch, Mr. Alex. Don, Mr. Alex. Mitchell, Dr. George Rose, and the President took part.

Mr. G. H. Colt read a paper on the results of the treatment of cases of

Acute Appendicitis

occurring in Prof. Marnoch's wards in the Aberdeen Royal Infirmary from January, 1911, to December, 1921. There were 675 cases of which 568 (84 per cent.) were operated on within 24 hours of admission and 107 were kept under observation, 92 of the latter being subsequently operated on without mortality and a definite lesion of the appendix found in all of them. The mortality in the 568 cases operated on urgently was 6·3 per cent., but excluding 7 cases of wrong diagnosis with two deaths, one being a case of volvulus and one a case of small ovarian cyst from which streptococci were isolated, the mortality was 6·07 per cent. In 94 cases without pus it was 1·06 per cent. drained and in 165 such cases not drained 1·81 per cent. In 170 gangrenous cases the mortality was 8·82 per cent., in 62 perforated cases 11·3 per cent., and in 99 abscess cases 3·03 per cent. The chief conclusions were: (1) about 84 per cent. of acute cases require urgent operation; (2) about 90 per cent. of all cases requiring urgent operation will suffer primary appendicectomy; and (3) when pus appears in a gangrenous case the risk rises from about 2·4 per cent. to 8·8 per cent. and in some third day cases to double this, the risk rising geometrically as the time increases arithmetically.

Prof. Marnoch and Mr. Smith contributed to the discussion, and some remarks from the statistical point of view were made by Dr. J. F. Tocher.

NORTH OF ENGLAND OBSTETRICAL AND GYNÆCOLOGICAL SOCIETY.

A meeting of this Society was held in the Liverpool Medical Institution on Feb. 16th, Prof. W. Blair Bell in the chair.

Aveling's Repositor.

Dr. Miles H. Phillips recorded a case of chronic inversion of the uterus to emphasise the value of Aveling's repositor. A complete inversion of uterus and cervix was discovered four months after confinement. After the necessary attention to the local toilet, the repositor was introduced and completed its work within 12 hours. He had had two small holes bored through the head to relieve the difficulty previously experienced in removing a repositor with a solid head, owing to suction between it and the uterus. This has been completely satisfactory. He further emphasised the slight pressure required. It was furnished by two rubber "paper bands."

Miss F. Ivens said that as a house surgeon she had used the repositor; the patient had had to be kept under morphia owing to severe pain; the suction between the head of the repositor and the uterus had caused difficulty in removal.

Dr. A. Donald had found the repositor successful in four cases.

Dr. J. H. Willett had had no difficulty in applying the repositor on one occasion, but it had entirely failed after 48 hours. In this case the inversion had only been discovered some time after confinement, and involution was complete. At operation the peritoneal surfaces were found adherent to one another, evidently owing to infection; this was supported by the occurrence of phlegmasia alba dolens after the operation.

Dr. Fletcher Shaw agreed that the peritoneum in some cases might be damaged and adhesions develop. He cited an acute inversion he had seen: primary treatment to relieve the shock, and 24 hours later reduction of the inversion under ether. A fortnight later the abdomen had to be opened for intestinal obstruction—coils of intestine were found adherent to the uterus.

Dr. Phillips, in reply, agreed that the repositor would probably fail in cases where adhesions were present; so far he had found it uniformly successful.

Dr. Leith Murray, Dr. Meredith Littler, Dr. Ruth Nicholson, Dr. Pickering Jones, Dr. Willett, Dr. D. Dougal, Prof. H. Briggs, Miss Ivens, and Dr. Fletcher Shaw showed cases and specimens.

DEVON AND EXETER MEDICO-CHIRURGICAL SOCIETY.

A meeting of this Society was held at the Royal Devon and Exeter Hospital on Feb. 22nd, Dr. G. P. Hawker, the President, being in the chair.

Dr. R. V. Solly read a paper on

Some Laboratory Tests in Diabetes.

He began by reviewing the modern theories of diabetes, particularly with regard to the experiments of Allan and others with reference to depancreatised dogs and the influence of the hormone from the islands of Langerhans on the metabolism of sugar, and he touched on the mechanism regulating the blood-sugar in relation to the endocrine glands generally and also the special centre in the brain acting through the splanchnic nerves. He then referred to estimations of blood-sugar and laid stress on the importance of carrying out a glucose-tolerance test, with estimations every half hour for at least two hours, according to the method described by H. Maclean, and the plotting out of the results as a curve. A single estimation of blood-sugar taken at any time without relation to meals was of little value. He showed curves of estimations he had carried out in normal persons, renal diabetes, the "lag" curve, and cases of true diabetes. He then attempted to give a definition of acidosis and advised the following tests in such a condition: 1. The tests for acetone bodies in the urine. 2. The ammonia coefficient in the urine. 3. Estimation of the CO_2 in alveolar air. 4. Estimation of the sodium bicarbonate content of the blood plasma.

Dr. F. A. Roper emphasised the value of blood-sugar curve estimations as a guide not only in lesser or occasional forms of glycosuria, but in severer forms of true diabetes, where they are a gauge of the results obtained by dietetic treatment. He also showed charts illustrating the altered ammonia coefficient and the importance of accurate knowledge of the degree of acidosis present. Protein and fat restriction had to be as carefully considered as carbohydrate restriction in successful dietetic treatment. Different methods of arriving at a standard diet after abolition of the glycosuria by fasting were described, though as long as effective treatment remained as at present simply dietetic many disappointments in results must always be inevitable. Administration of alkalies appears to be of very limited value whether in acidosis or in coma.

The President commented on the fallacies which so frequently arose through the Fehling reduction test.

Dr. W. Gordon compared the hopeless condition of the young diabetic of earlier days—with rapid progression towards the stage of coma—with the effects now observed under the Allan and other enlightened treatment. There were often, however, cases where we found ourselves between the alternatives of starvation and coma. He had seen a recent young case where glycosuria, obviously related to a continuous surfeit of loaf sugar, had cleared up altogether. He had also seen good results from salicylate of soda in the glycosuria of the young. The insulin treatment must yet be considered with reserve and he deprecated the publicity given to it in the daily press.

Dr. B. Cohen raised a question as to the dieting of a diabetic affected with pulmonary tuberculosis.

Mr. A. L. Candler quoted a striking case of septicæmia arising from a wound in the foot where the glycosuria and acetonæmia had tended to disappear after amputation of the limb.

Dr. P. D. Warburton said that acidosis became negative on the advent of diabetic coma.

Dr. H. Jonas mentioned the importance of glucose injections as a prophylactic against the toxæmia and jaundice arising from salvarsan injections.

ROYAL MEDICO-CHIRURGICAL SOCIETY OF GLASGOW.

A meeting of this Society was held on Feb. 16th, when Dr. J. Ferguson Smith made a communication on

Some Points in the Ætiology of Eczema.

The conclusions arrived at were: 1. The skin of eczema patients is not abnormally sensitive to all irritants. 2. The skin of a patient, or an experimental animal, sensitised to a protein, is not more sensitive to a non-specific irritation than that of a normal person or animal. The sensitiveness is specific. 3. Attention was drawn to an important class of case in which eczema appears to be due to sensitiveness to skin bacteria.

Dr. Ivy MacKenzie made a communication on Psychotherapy and the Orthopædic Problem.

Reviews and Notices of Books.

ORAL ROENTGENOLOGY.

A Roentgen Study of the Anatomy and Pathology of the Oral Cavity. Second edition, revised and enlarged. By Kurt H. Thoma, D.M.D., Assistant Professor of Oral Histology and Pathology and Member of the Research Committee, Harvard University Dental School. London: Henry Kimpton. 1922. Pp. 341. 30*s.*

This is an instructive book. The full description of the operative and pathological conditions of the cases quoted, as well as the clear account of technical procedures, make it of great practical value. It is divided into six parts. Dr. Thoma starts with an account of X rays apparatus and different forms of tubes. The interrupterless transformer is well described and reference is made to the efficiency—although limited—of the special dental X rays outfits now on the market. In the next section, on Application of the Rontgen Rays, the author deals first with the protection of the operator and patient, and then describes the technique of dental radiography, adding a useful exposure table. In discussing intra-oral films, he explains at some length, with excellent illustrations, the angle at which the rays should be directed so as to avoid distortion. The student reader should give this description especial attention.

The method for obtaining extra-oral radiographs is next given and their advantages are discussed, but the technique described for taking the sinuses would, we think, lead to much discomfort to the patient; this is a factor of importance, because if a patient is not comfortable he cannot keep still for any length of time. The value of stereoscopic radiographs makes no strong appeal to Dr. Thoma, who considers the "two position" method as sufficient in most cases. He gives some space to stereoscopic intra-oral films; the value of these we consider doubtful owing to their smallness and consequent paucity of objects, an objection which does not occur with extra-oral plates. A chapter is devoted to development of films, while another most useful one deals with causes of poor results.

Part II. is devoted to Interpretation. The author recognises the importance of the clinical conditions and approximate age of the patient being borne in mind when making a radiological diagnosis. In the chapter on Misinterpretation several common fallacies are pointed out. We should have liked to have seen more space devoted to the Rontgen appearance of teeth and jaws during development, although the illustrations and their descriptions are certainly helpful. The radiographic appearances of normal adult jaws and teeth are well defined and copiously illustrated. Part III. deals with Rontgenographic Study of Normal Oral Tissues in all stages of development. Part IV., on Rontgenographic Study of Pathological Oral Conditions, consists of 155 pages and deals first with abnormal dentition in its various forms. Diseases of the hard tissues of the teeth and of the dental pulp and their sequel, peri-apical infection, are adequately dealt with; the author emphasises the value of the X rays (p. 165) in the detection of the chronic blind abscess now recognised as being such a fruitful source of systemic infection. The nomenclature used in this book is, we must observe, different from that used in the United Kingdom; this is especially noticeable in the chapter on Periodontoclasia, defined as pathological changes causing destruction of supporting structures of the teeth. The statement in the chapter on Diseases of the Maxilla and Mandible that necrosed bone is recognisable in radiographs by its irregular outline should be limited only to necrosis when it is sequestrated; otherwise the condition is not possible to demonstrate by the X rays, although it may be apparent clinically. The illustrations of cases of osteomyelitis are very interesting. Dr. Thoma considers dental infection the most frequent cause of antral trouble; in this country there are many who consider infection from the frontal sinuses to be the most frequent cause. As to dental cysts invading the maxillary antrum, in our experience it is frequently difficult to discern in a radiograph where the one begins and the other ends. Part V. of the book is devoted to an excellent exposition of the use of Rontgenograms as an aid in treatment. Under the heading Apicoectomy, the author suggests that after this operation has been performed radiographs should be taken from time to time to watch the process of repair, and a series of radiographs of cases is given. With this suggestion we quite agree, but would go further and suggest that a definite line of research be made of the healing that takes place, in the interests of conservative dental surgery. With the instructions on examination of the oral cavity in Part VI. we concur, also with Dr. Thoma's view as to the importance of a careful and more thorough examination than is usually made.

We can confidently recommend this book to all interested in this valuable branch of modern science.

STERILITY IN WOMAN.

Its Causes and Treatment. By Robert A. Gibbons, M.D. London: J. and A. Churchill. 1923. With 44 illustrations. Pp. 244. 12*s.* 6*d.*

Dr. Gibbons has already established a claim to be regarded as an authority on the subject of sterility, and this work will strengthen that position. It is written clearly and should make a special appeal to the general practitioner. The book is divided into six chapters of which the first deals with sterility and the State. It begins with definition and classification, and the author defines sterility as "the inability of a woman to bring forth living children." This is hardly a satisfactory or even an accurate definition; it implies that a woman who has had half a dozen stillborn children is sterile. A truer definition of sterility would be failure to conceive on the part of a woman who has had sufficient opportunity therefor. Certain formal defects in the method of classification of the causes are also apparent, but they do not impair the practical value of the book, except in so far as a careful systematic investigation of causation may be necessary in a given case before treatment is undertaken.

The section on sterility and the State is one of the most stimulating in the book. The author advocates several measures which would hardly meet with general acceptance at the present time; for example, notification of venereal disease, the production of a certificate of health as a necessary preliminary to marriage, and the sterilisation of those who are physically or mentally unfit to beget healthy children. Dr. Gibbons utters a solemn protest against the prevalent indiscriminate practice of birth control. Chapter 2 is a clear exposition of the anatomy of the pelvic organs and the physiology of conception, and contains also a summary of the causes of male sterility. Chapter 3 deals with the structural causes of sterility. In discussing the relation of fibroids to sterility the author draws attention to the frequent association of uterine fibroids with tubal inflammation. Among other useful information on functional sterility there is a good summary of recent work on the effects of diet, and of Prof. Arthur Robinson's valuable investigations on prenatal death. Such slender information as we possess on derangement of endocrine organs is also included. Chapter 5 is on medical treatment. It contains a section on "induced sterility" in which the author gives a thoughtful account of the effects of purposeful interference with the normal marriage function based upon his wide experience. The practitioner will find many useful suggestions in this chapter. The last chapter is devoted to operative treatment and most of it is sound. We are disposed to take exception to the recommendation of Pozzi's operation for "pin-hole" os; the result resembles too closely the effect of a bilateral tear of the cervix. A thorough dilatation nearly always answers the purpose; and if some form of plastic operation is required, Dudley's method is better. Conservative procedures on the tubes are fully described. For fibroid tumours of the uterus, the author leaves the impression that conservative myomectomy has a very restricted field, whereas this operation is in fact the practice of many well-known gynæcologists in women under 30, when surgical treatment is required. Cæsarean section comes in rather quaintly among operations for the cure of sterility.

We can heartily recommend this useful and well-written book.

PATHOLOGY.

Traité de Pathologie Médical et de Thérapeutique Appliquée. Par EMILE SERGENT, L. RIBADEAU-DUMAS, L. BABONNEIX. Vol. XIII.: Reins et Organes Génito-Urinaires. Paris: A. Maloine et Fils. 1923. With 61 figures. Pp. 891. Fr.35.

THIS volume is divided into three sections, of which the first, written by MM. M. A. Brault, M. J. Cottet, and E. Michon, deals with the anatomy, physiology, and diseases of the kidney; the second section, contributed by MM. M. A. Louste and H. Lemaire, includes diseases of the genital organs; the third section, by M. R. Hazard, deals with analysis of the urine. The authors succeed in giving an admirable review of modern French thought and work on diseases of the urino-genital system. The student of medicine will find the treatment of the several subjects somewhat discursive; there is, moreover, a lack of exact clinical description and scanty reference to work done in other countries. No references to publications are given. The section dealing with Bright's disease is the most important since it ably summarises the work of the French school on the chemical pathology of renal disease. A strong effort is made to classify nephritis in terms of functional derangement in place of structural change. Retention of chlorides and nitrogen are discussed at length, and methods of testing renal function are well described; the treatment of the subject on these lines fails to carry conviction only because so little is yet known of the physiology of the kidneys. The treatment of the several diseases and clinical conditions is well given and concisely stated. The last section of the book dealing with analysis of urine is perhaps the best. It is well arranged and contains a great deal of exact information.

PSYCHO-ANALYSIS.

Our Unconscious Mind and How to Use It. By FREDERICK PIERCE. London: Kegan Paul. 1922. Pp. 323. 10*s.* 6*d.*

MR. Pierce is energetic if unscientific; he turns psycho-analysis into a business proposition. Control and operation of the will; raising successful children; growing abler instead of growing older; setting the unconscious mind at work; a business organisation that will get more done—these are some of his aims, and he has no doubt whatever how they may be achieved. To the victim of smoking who cannot stop the habit, he begins an address with: "What is to be done? First there should be a searching and honest analysis of every important instance of wavering resolution; the opposed wishes should be examined by association until all of their elements are revealed. This will sometimes lead to surprising discoveries; so much the better. Knowledge is the first step toward resolving a conflict" (p. 64). Auto-suggestion is also a strong line: you get into a proper state of mind and select a goal "which is practical and which will harmonise with a basic wish of the Unconscious." If you have any trouble in finding such a wish, the book will direct you. Endocrinology, too, seems a good seller: "pituitary variance and adrenal insufficiency" is a frequent diagnosis that admits of no doubt and apparently needs no explanation, whilst pathological lying and stealing sometimes need correction of the pituitary or thyroid, which "may result in a tractable, happy child, with fine mental ability" (p. 151). The final chapter on "The New Psychology in Selling" tells the salesman how to guess the soft side of a flinty customer, and warns him not to try to sell his wares to the husband when he should have sold them to the wife.

Efficiency is a good motto, but the old-fashioned reader is likely to be alarmed at the prospect of forcefulness and uplift offered by this book.

INFANT FEEDING.

Feeding, Diet, and the General Care of Children. By ALBERT J. BELL, A.B., M.D., Assistant Professor of Pediatrics in the Medical Department of the University of Cincinnati; Attending Pediatrician to the Cincinnati General Hospital. Philadelphia: F. A. Davis Company. 1923. Pp. 276. $2.00.

This little book is written for the mother and trained nurse. The sections are well arranged, and paragraphs and the use of bold type simplify reference. Feeding tables are given and can be easily understood. The author recommends four-hour intervals for feeding, and increases with age the concentration of cow's milk in his milk mixtures. He is, on both these counts, at variance with some English authorities. We question the safety of advising two quarts as a suitable quantity to give an infant as an enema, and also the necessity for directions as to catheterisation. On p. 132 it is recommended that the daily evacuation of the bowels should be obtained before a meal, which seems hardly physiological.

The book is written with understanding, and should prove useful to nurses and educated mothers, working under the direction of a physician, provided the latter agrees with the author as to methods of milk dilution.

Principles and Practice of Infant Feeding. Third edition, revised and enlarged. By JULIUS H. HESS, M.D., Professor of Pediatrics, University of Illinois College of Medicine. Philadelphia: F. A. Davis Company. 1922. Pp. 496. $4.

IN this volume, which is the third edition of Dr. Hess's work, some of the chapters have been rewritten, and new chapters on rickets and spasmophilia are added. After a short account of metabolism in the infant, the author deals with nursing and artificial feeding in two chapters. Principles are enunciated upon which the diet is to be arranged, using the calorie requirements of the infant as a basis. Nutritional disturbances are discussed under a classification modified but definitely following Finkelstein. Intraperitoneal saline is recommended in anhydræmic conditions as the most suitable method of supplying fluid. The chapters on rickets and scurvy give an account of recent work on the subject, but English workers are rarely quoted. The subject of anæmia is dealt with too briefly to be of real value, and would anyhow seem out of place in a work on infant feeding. We cannot agree with the author in his statement that congenital pyloric stenosis is a frequent form of obstruction, nor in his consideration of the condition as a minor disturbance. But apart from these points the book is a valuable one.

THE ELEPHANT MAN AND OTHER REMINISCENCES.

By Sir FREDERICK TREVES, Bart. London: Cassell and Co. 1923. Pp. 222. 7*s.* 6*d.*

ANYONE who has worked for years in a great hospital must have accumulated a store of facts dealing with various aspects of human nature in which the pathetic and the comic are intimately blended. Few, however, put their recollections into print, and still fewer could do so with the blend of humour and charity which characterises Sir Frederick Treves's present book. The first paper, which gives the title to the volume, is a story of one who was sorely tried and who might have said in the words of the Psalms, "I am become as it were a monster unto many; but my sure trust is in thee." John Merrick was afflicted with a hideous deformity affecting both the osseous structures of his head and face and also the skin of his body. How he came under the charge of Sir Frederick Treves must be read in the book; suffice it to say that when he did so he was barely human, more like a hunted and frightened animal. For years he had been turned over from one showman to another to be made a gazing stock and a mockery, and his case was all the more sad in that he was in no way imbecile, but intelligent and conscious of his unhappiness. After he had found an asylum in the London Hospital his one fear was that he should be moved on somewhere else, for his life had been hitherto spent in transference from one showman to another. His pathetic appeal to Sir Frederick Treves was, "When I am next moved can I go to a blind asylum or a lighthouse?" In the former, though in company with his fellows, he could not be seen; in the latter, "a lonely column of stone in the waste of the sea," there would be no one to see him. We should add that we have received a cutting from *The World's Fair* for Feb. 24th containing a letter from Mr. Tom Norman, one of the showmen who had "a business interest in Joseph Meyrick (not Merrick)"; he says that Meyrick was only on exhibition for about 30 months, and never in a caravan. Many of the other chapters are well worth reading; the second episode in that entitled "Two Women" is one more example of the devotion shown by women to the men to whom they are bound by regular or irregular ties. Such devotion is often found in real life and forms a stock situation in fiction.

JOURNALS.

JOURNAL OF PHYSIOLOGY. Vol. LVII. Nos. 1 and 2. Among the papers in these numbers of the journal are the following: The Metabolism of the Salivary Glands, by G. V. Anrep and R. K. Canaan. The previous investigations on the blood-sugar metabolism of these glands showed that the resting gland consumes blood-sugar at a fairly constant rate and that this rate is greatly increased under the influence of pilocarpine—the increase being in broad proportion to the activity of the gland as measured by the flow of saliva. The authors find that changes in the blood flow through the gland do not affect the consumption of sugar from the blood, and that stimulation of the chorda tympani increases the blood-sugar consumption. The increase is of the same order as that of the gland secreting under pilocarpine, and is broadly proportional to the activity as measured by the rate of secretion. The maximal consumption of sugar corresponds with the maximal secretion and does not occur, as does the oxygen consumption, in the post-active period. Atropine in doses sufficient to paralyse the secretion only reduces the effect of the chorda tympani on the sugar consumption. Large doses abolish the effect altogether. As regards the reducing substance of the submaxillary gland, Anrep observes that mucin is the chief product of the synthetic activity of this gland in the dog and is the main form in which nitrogen is excreted by the gland in activity. Mucin contains in its molecule a reducing substance—glucosamine—and can be traced not only by the nitrogen determination but also by its reducing substance which it yields upon acid hydrolysis. It was found that the gland loses the same amount of reducing substance as is secreted in the saliva.—On the Nature of the Sugar in Blood, by L. B. Winter and W. Smith. The authors describe their method whereby the sugar of blood can be obtained in a concentrated solution free from proteins, and it is shown that the sugar in normal blood of man, and of the ox, sheep, cat, and rabbit is an unstable form of glucose, with an initial low rotatory power. It is suggested that the sugar is γ glucose. Glucose and fructose taken in large quantities per os could be detected as such in the blood, their conversion into normal blood-sugar being very rapid. Nervous influences alter the nature and quantity of the blood-sugar. The blood-sugar of persons suffering from severe diabetes mellitus is of an abnormal nature. It appears to be α, β form of glucose. An enzyme is postulated, whereby the α, β equilibrium form of glucose is converted into γ glucose. This enzyme is absent from the blood. The absence or inactivation of this enzyme is suggested as the cause of diabetes.—Respiration and Circulation in the Cat, more especially as to the Oxygen in the Venous Blood of the Resting Animal, by K. Uyeno and Y. Doi. The authors find that in any given vein the percentage saturated with oxygen varies widely; it varies independently in different veins in apparently similar conditions of urethane anæsthesia, and it bears no relation to the blood in the right ventricle.—Circulation After Cessation of Work, with some Remarks on the Calculation of Circulation-rate Experiments according to the Nitrous Oxide Method, by J. Lindhard.—Season Variation in the Reticulated Corpuscles in Amphibian Blood, by J. M. P. Scott. The blood of the frog and toad shows a high proportion of reticulated cells in late summer, which persists for some time. In late spring and early summer prior to the crop of new reticulated cells, the proportion of reticulated cells falls to a minimum. The majority of red cells of the frog and toad pass through their complete cycle in the course of a year.—Chlorine Interchange Between Corpuscles and Plasma, by Lucien Dautrebande and H. Whitridge Davies. In all the experiments normal human blood was used, clotting being prevented by the addition of a constant small amount of neutral potassium oxalate (0·1 per cent.). In all the experiments with carbon dioxide and with other acids, the blood was fully oxygenated. The authors' results with CO_2 are in accordance with those of previous observers. With constant partial pressure of carbon dioxide, reduction of hæmoglobin produces no chlorine transference. Acids other than carbonic acid, whether added to the blood in vitro or produced in vivo, do not of themselves cause any chlorine transference unless they be present in quantities sufficient to neutralise the whole of the bicarbonate reserve. Experiments with severe muscular work appear to indicate that chlorine transference may occur not only for the regulation of the blood alkalinity, but also possibly to maintain the normal osmotic pressure in the plasma.—Calibration of the Reversion Spectroscope for the Estimation of CO in Blood; and on Visual Acuity and the Resolving Power of the Eye, by H. Hartridge. The author deals successively with the histological and optical limits to resolving power, visual acuity for contours, the relation between the form and position senses and visual acuity, the difference threshold of the foveal cones for light intensity and factors affecting the difference threshold for light intensity.—The Relation between the External Work Produced and the Time Occupied in a Single Muscular Contraction in Man, by Hartley Lupton. It has been shown experimentally that the maximum work done in a single muscular contraction in man depends in a simple exact manner upon the mass moved or upon the time occupied in the movement. The author's experiments show that rapid movement means large internal friction and large loss of energy as heat, the external work produced by the muscular contraction being thus considerably less than the original potential energy possessed by the muscle. In the muscles of the human arm a movement completed in one second wastes 26 per cent. of its energy in overcoming the frictional resistance of the muscle itself, a movement completed in half a second some 52 per cent., until in a movement completed in about 0·26 second no external work can be done at all. Yet the movements of the wing muscles of insects are enormously more rapid than this. Presumably the structure of the insect's muscle is modified in some way to allow those movements to occur without the extreme wastefulness associated with rapid movement in man.—On the Concentration of the Blood and the Effects of Histamine in Adrenal Insufficiency, by C. H. Kellaway (see annotation, p. 556).

THE LANCET.

LONDON: SATURDAY, MARCH 17, 1923.

IS INFANTILE DEATH-RATE SELECTIVE?

> "We may regard the weight of present evidence as altogether preponderant in favour of the view that the death-rate of the earliest period of life is selective—eliminating the weak and leaving the strong."

This dogmatic statement appears in Prof. Raymond Pearl's recent monograph on the "Biology of Death," and we turn with interest to the evidence on which this statement is based. It is a statement which has important bearings on the value of maternity and child welfare work in this and in all countries; and it has at the same time a bearing, to use again Prof. Pearl's words, upon "a great deal of the public health propaganda so loosely flung about." It is common ground that the inheritance factor is of prime importance in determining the length of the life span. In some families longevity, given satisfactory methods of life, is the rule; and even unsatisfactory methods of life are less potent in shortening life than when indulged in by others without the same happy heredity. But the question remains whether in the first two years after birth environmental factors are to be regarded as relatively insignificant compared with inherited capacity for life. To take concrete examples, is the 24 per cent. excess of mortality of infants in the urban districts of England in 1920 over that in rural districts due to inherited superiority of the rural population or to differences of environment or to both? Similarly, to what are we to ascribe the fact that in county boroughs in the north the infant mortality is 46 per cent. above and in county boroughs in the south of England it is 35 per cent. below the average for the entire country? Or if we take the infant death-rate per 1000 births within the first month after birth, why is this only 19 in Oxford and 56 in Barnsley? Can selection account for these differences; or may we not rather conclude that selection, to the extent to which it does act, is a force of not greatly dissimilar quality in different parts of the country, and perhaps also in different social strata of the population, and that the greater part of the serious discrepancies in infant mortality is due to differences in total environmental circumstances? The range of operation of environment on the human organism is seldom adequately visualised, and especially the extent to which infection and defects of nutrition influence mortality, whether occurring in ante-natal or post-natal life.

The acute discussion on this problem dates from the appearance of the first report on infant mortality issued by the Local Government Board in 1910 (Cd. 5263). This report, written by Dr. Arthur Newsholme, then Principal Medical Officer of the Board, gave as one of its main conclusions that "the continuance of a high infant mortality in a given district involves the continuance of a centre of national weakness"; and that, "without attempting to settle the moot point as to whether a heavy infant mortality has any selective influence on the population surviving after infancy, in actual experience the effect of any possible natural selection is most effectively concealed by evil environment which causes the hypothetically stronger survivors to suffer from excessive mortality in youth and adolescence, so far as they can be traced." In this conclusion, which points to the supreme importance of environmental reform, no separation could be made between groups in the same population exposed respectively to low and to high infant mortality and severally traced in later life. But so far as the data went they established the conclusion that "a high infant mortality implies a high prevalence of the conditions which determine national inferiority." Dr. E. C. Snow, one of Prof. Karl Pearson's students, investigated the problem further, attempting to trace infants born in a single year through successive years. He employed the method of partial correlation, a method on the merits of which biometricians appear to be violently divided. Using English and Prussian statistics, he found negative correlations between the death-rate in infancy and in successive years of life, which is consistent with the conclusion that mortality in early life is selective. Although environmental evils in many areas "account for much," he concludes that "the more children who die below the age of 3 years, the healthier the next five years of life." At this point the controversy was taken up by Dr. John Brownlee in a paper on the Relation of Infant Mortality to Mortality in Subsequent Life.[1] He indicated that Prof. Pearson, who had emphasised and extended Dr. Snow's conclusions, had employed a method of investigation considered by Dr. Brownlee to be "fundamentally fallacious," that the epidemiological aspect of the statistics had been neglected, and that in fact when other data were employed the negative correlation found by Dr. Snow became a positive correlation! It is not surprising in view of these discrepant results that Dr. Brownlee regards partial correlation coefficients as a labyrinth without a clue. He concludes that full inquiry throws doubt on every method which has been proposed to measure the influence of the death-rate as a selective agent.

The death-rates in infancy which we have quoted, with their enormous range, justify the welfare work which has been one of the most important recent developments in public health activities. These ranges of mortality cannot be satisfactorily explained on the hypothesis of natural selection. Areas of excessive and of low infant mortality stand in proximity to each other, in different towns, in town and country, in different wards of the same town, in neighbouring streets. To refer these differences of mortality and of accompanying damage without death, entirely or chiefly to initial faults of parent age is unjustified by the facts; and is, furthermore, disproved by the immense improvements in infant mortality generally and in the special areas in which infant mortality was excessive and in which intensive child welfare work has been done. Prof. Pearl informs us that "happily" Pearson's and other results showing selective death-rates have been amply confirmed. Were this so the "happiness" of a multitude of medical and social workers would be sadly diminished; but for the present they can confidently pursue their important work, in the conviction that by so doing they are doing more for the up-building of race improvement than is practicable on any other lines.

THE SURGICAL TREATMENT OF SPASTIC PARALYSIS.

The discussion on spastic paralysis and its surgical treatment at the meeting of the Section of Orthopædics of the Royal Society of Medicine, of which a report will be found on p. 537, deals with an important and difficult subject. The treatment of this disability has always presented and still presents great obstacles to success. In most other conditions which the orthopædic surgeon is called upon to treat he has to deal with deformities and disabilities in the cure of which he may reckon sooner or later on the coöperation of the patient. In infantile spastic palsy, unfortunately, the defect in the upper motor neuron is accompanied in the vast majority of cases by defect of the higher cerebral centres, and the mental condition varies in any series of cases from normal intelligence to complete idiocy. It is obvious that it is of no use to remove the physical obstacles to the normal use of the limbs if there is not enough intelligence to direct their movements. This is well recognised, and Mr. Blundell Bankart and the other speakers at the meeting were all agreed on this point.

Spastic infantile paralysis was first brought to the notice of the profession in 1843 and again in 1861 by Dr. W. J. Little, who, at the later date had seen and treated some 200 cases. At that time and for long after the treatment consisted of exercises, manipulations, retentive appliances, and tenotomy of contracted tendons, but not many surgeons, it is to be hoped, emulated Jules Guerin, who declared that at one sitting he had divided 60 muscles and tendons. Until some 14 years ago little or nothing had been done to attack the problem on its neurological side. In 1909 Foerster and Kuttner, of Breslau, applied to the relief of spasm Abbe's operation of division and resection of posterior nerve roots, which had previously been used to relieve severe pain. By thus breaking through the reflex circle, spasm could be abolished. They published a number of brilliant results—so brilliant as to appear almost incredible. British surgeons who followed their methods did not obtain like successes and this method of treatment was soon abandoned, to be remembered as a glaring example of the untrustworthiness of a certain kind of medical and surgical "boom." The method described and advocated by Mr. Bankart is that popularised by Stoffel, who made use of the anatomical fact that the motor nerves to muscular groups, or even to individual muscles, may be distinguished as separate bundles in the main nerve-trunks for a considerable distance above the points where they diverge. Here they may be singled out and, after electrical proof of identity, divided in whole or in part according to whether it is thought necessary to paralyse a muscle entirely or only to do so partially. By this method the reflex circle is broken on its efferent side. Of late years orthopædic surgeons have put forth determined efforts to get rid as far as possible of cumbrous retentive appliances, representing a sore burden on locomotive systems which are already damaged. Mr. Bankart claimed as one of the merits of Stoffel's operation that it did away with or at least minimised after-treatment and the use of walking apparatus, and although his claim was not allowed in full by other speakers, it was generally admitted to be sound.

In the ensuing discussion the President, Mr. T. H. Openshaw, and others who had no personal experience of Stoffel's operation, expressed themselves as not opposed to it, while those surgeons who had experience of the method were in favour of its adoption in appropriate cases for the lower extremity, although they generally expressed the opinion that it could not entirely displace older methods such as lengthening of the tendo Achillis. A consensus of opinion was unfavourable to the operation in the upper extremity, where the resulting paralysis was held to be a drawback. Excision of the tendon and transfer-transference were preferred as giving better functional and equally good æsthetic results. Everyone present recognised, however, that the functional success of any treatment depended very largely on the mentality of the patient. No one had a word to say in favour of Foerster's proceeding, which its author himself is said to have now abandoned. The neurologists who took part in the discussion spoke favourably of Stoffel's operation and welcomed the abandonment of posterior root-section. Experience shows that relief of spasm and the consequent development of powers of locomotion is an end not only to be sought after for itself, but also because of its apparently beneficial effect on the mental condition in many cases. We say apparently, because it is difficult to decide how much of the mental improvement is due to natural, if delayed, cerebral development as the child grows older, and how much to the improved condition of the locomotive apparatus, due to surgical treatment. Some distinguished orthopædic surgeons in this country and America attach very great importance to what is not very aptly called re-education. Their views were scarcely represented in the discussion, although everyone must admit that training in the use of the limbs which have been liberated from the tyranny of spasm has its place in the after-treatment. The parents and friends of these children, even of those of very low mentality, are in general very much attached to them, sometimes lavishing more tender affection on them than upon their normal brothers and sisters, and they frequently hold pathetically optimistic opinions as to their mental capacity. They highly value every improvement, however small, and it becomes the duty of the surgeon not to neglect any means of amelioration and not to pronounce any case as hopeless until he has given it most careful and prolonged consideration. The Council of the Section of Orthopædics is to be congratulated on having arranged for the discussion of this subject, which alone would be enough to justify the comparatively recent conversion of the subsection into the present vigorous and flourishing section.

◆

BOTULISM: A RARE DISEASE.

In the process of transition from a purely clinical to an ætiological classification of any group of diseases a stage must be reached where the newer method of division overtakes and cuts across the older, while neither can stand alone. For a time our concept of a disorder vacillates between that of a clinical syndrome not necessarily referable to one organism, and that of a specific infection or intoxication produced by a known virus. The definition of some diseases is already crystallised; for example, diphtheria takes its place as a specific invasion by the Klebs-Löffler bacillus; but, on the other hand, disseminated sclerosis suggests only a complex of nervous and mental symptoms, and the same may still be said even for some pathological states, such as general paralysis of the insane, of which at least the remote ætiological factor is accepted. When the necessity arises to determine the nature of diseases of a more or less unusual incidence, because the origin of a symptom-complex may be of vital import to the community, any ambiguity in classification that may lead to confusion must be strenuously fought. A notable example is the misapplication of the term "botulism" to numerous cases exhibiting miscellaneous encephalic symptoms thought to present a clinical picture, without regard either for the history or specific ætiology of the cases. Dr. W. G. SAVAGE in the third of the Milroy Lectures, which we abstract on another page, goes so far as to say that, so far as he can trace, the Loch Maree outbreak[1] is the only outbreak of botulism which has occurred in England. In a review of the subject in the current issue of *Medical Science, Abstracts and Reviews*, it is pointed out that while the classical picture presented by victims of botulism, especially the persistent ophthalmological symptoms combined with a normal disc, and the absence of fever, tend to make it a nosological entity, the differential diagnosis is not easy. Poisoning with certain plant alkaloids, particularly belladonna, on the one hand, and asthenic bulbar paralysis on the other, present real puzzles in differentiation. In fact, the most certain guide to diagnosis is the evidence of food poisoning in individual cases and that of commensalism in an outbreak.

From an analysis of several cases in a proved outbreak of botulism two points stand out: firstly, that cranial-nerve paralyses are constant symptoms; they frequently precede the gastric symptoms in food poisoning from this cause, and they may constitute the whole clinical syndrome. Secondly, the time of onset of symptoms varies to such an extent that the poisoned individuals may scatter widely and the presence of an outbreak may escape recognition. Though it is by serological means that the diagnosis is most definitely established, in practice successful treatment by antitoxin depends mainly upon early clinical diagnosis. Confirmation of the contamination of the suspected foodstuffs is important, as is also the establishment of the particular type of toxin responsible for the symptoms. There appears to be no doubt as to the therapeutic value of the serum if administered early, and thus a supply of a polyvalent antibotulinus serum should be readily available for distribution.

The increase in the recently reported cases of food poisoning in America has been explained by the fact that as a result of the world's shortage of food, the Federal authorities have been urging the necessity of canning fruits and vegetables at home. It is suggested that home canning cannot be as effective as that undertaken commercially, and that spores which do not escape professional handling may resist the efforts of the amateur; tests undertaken by E. C. DICKSON and others appear to confirm this possibility. Dr. SAVAGE states (p. 529) that in 84 outbreaks of botulism in the United States and Canada, all derived from canned or bottled foods, comprising 319 cases with 206 deaths, 52 were from home and 31 from commercially canned foods, 1 being doubtful. The toxins or bacilli are easily killed by heat, but the spores of *B. botulinus*, which are even more prevalent in virgin than in cultivated soil and may gain access to canned foods, are exceptionally resistant. However, he concludes that the risk of botulism from canned foods, though a real, is a very small one, and with added care can be still further diminished.

Annotations.

"Ne quid nimis."

AN EXPLANATION OF THE HOUSING PROBLEM.

RECENT political events have again underlined the importance of the housing problem. There is no need to emphasise in these columns the vital connexion between housing and public health; the latter, whether physical or moral, is perhaps more dependent upon good housing than upon any other single factor in national affairs. Apart from the medical aspect of the problem, those who wish to consult a compact and authoritative account of the present position with regard to housing will find it in the typewritten *Monthly Record* of the National Housing and Town Planning Council, dated Feb. 23rd. This account has been prepared for submission to Members of Parliament; it discusses five definite points concerning which housing reformers throughout the country are in substantial agreement. The first point relates to the value of the housing schemes already carried into effect by local authorities. The number of houses completed under these schemes approaches 200,000 (the estimated need in 1919 was half a million). It is stated that these houses are tenanted by those for whom they were built, precedence having been given in 90 per cent. of cases to families of ex-Service men. About 85 per cent. of these houses contain three bedrooms. The designs of the houses are defended; apart from complaints on points of minor detail, it is claimed, the tenants are satisfied and appreciative of their bettered dwelling conditions.

Reference is made to the auxiliary housing policy embodied in the Housing Act of December, 1919. Under the provisions of this Act subsidies have been given (in sums ranging from £140 to £260) for upwards of 40,000 houses built by private persons. In the general experience of local authorities, who have signed the certificates under which the grants have been given, it is undesirable that this method of stimulating house supply should be repeated. Subsidies have been secured for the building of houses under conditions which constitute a grave misuse of public funds. It is estimated that less than one-third of the houses thus built are tenanted by members of the working classes. It may be urged that they have supplied the needs of the lower middle classes, but it is claimed that this result can in the future be achieved under far better conditions by the amendment and extension of the provisions of the Small Dwellings Acquisition Act. The cost of building the houses completed under the main scheme is the second point discussed; the third deals with the annual loss likely to be incurred in the event of adoption of new schemes. The fourth point relates to the new policy of coöperation with the State which has now found approval with the leading local authorities; the fifth is devoted to a series of proposals relative to the amendment of the Small Dwellings Acquisition Act. The influence of the operation of rings and trusts, and the industrial building boom which absorbed the energy of the building trade from 1919 to 1921, are clearly described, and the necessity is made plain for a bridging of the gap between the rent-paying capacity of the ordinary working-class tenant, whose wage standards have been greatly reduced, and the charges to be met in housing him.

THE TREATMENT OF PELIOSIS RHEUMATICA.

IN theory the choice of treatment should follow knowledge of ætiology of a disease. But it sometimes happens that a therapeutic bow, drawn more or less at a venture, adds to our knowledge of ætiology. This seems to have been the experience of Prof. E. Rautenberg[1] in his work on peliosis rheumatica, 23 cases of which he has treated in his hospital since 1915. As the name given to this disease suggests, its treatment has in the past been anti-rheumatic, and it has continued to be so, although the exhibition of salicylates and allied drugs has seldom had a prompt effect on the eruption, the sub-febrile temperature, the pain in the muscles, the swelling of certain joints, and the slight œdema of the skin often observed in this disease. Prof. Rautenberg's treatment is simple enough. He injects by lumbar puncture a local anæsthetic into the spinal canal, an average dose being 4 c.cm. of normal saline solution containing 0·5 per cent. novocaine. Under ordinary or expectant treatment with rest in bed, the rash takes at least a week or two to disappear, but after an injection of novocaine it often vanishes in a few hours, and never takes more than a day or two to do so. This phenomenon suggests that the rash is not due to actual extravasation of blood, but simply to distension of certain paralysed capillaries of the skin with blood. Microscopic examinations of sections of the skin by Dr. Walkhoff have shown dilatation of the capillaries, the lumen of which was not blocked by thrombi. There was also no sign of necrosis or proliferation of the endothelium; there was slight inflammatory œdema in the neighbourhood of the capillaries, the connective tissue being invaded by a serous effusion and numerous leucocytes. After giving detailed records of three cases in which the spinal injections afforded prompt relief, Prof. Rautenberg states that these were not specially selected cases, but that all the patients given this treatment responded in the same remarkable manner. He does not explain fully how he came to adopt this treatment, but he gives what appears to be a plausible explanation of its action. He thinks that the disease is not primarily peripheral; it is more likely that it begins as a lesion in the lower part of the cord, or in the cauda equina, and may be compared with the disease of the central nervous system which gives rise to herpes zoster. If this hypothesis is correct, the novocaine in the spinal canal may act by blocking morbid impulses travelling from the central nervous system to the joints, muscles, and skin, giving these structures a chance to recuperate. Prof. Rautenberg has given spinal injections of novocaine in certain other diseases associated with cutaneous eruptions, but with little success, and it would seem that such diseases as erythema nodosum, erythema exudativum multiforme, and the like, are in quite a different category from peliosis rheumatica.

CONGENITAL MALARIA.

DR. R. P. Forbes,[1] of the Department of Pediatrics in the University of Colorado School of Medicine, who records an illustrative case, draws attention to the rarity of intra-uterine infection with the malarial parasite. Beekel found only 12 examples of undoubted placental transmission of malaria on record up to 1910, one being under his own care, since when 15 more conclusive cases have been published. A summary of the reported cases shows, first, that all patients did not have symptoms when the plasmodia were found in their blood soon after birth, and, secondly, that symptoms appeared at various ages, the longest post-natal interval being seven weeks. A new-born child therefore may have a relatively latent type of malaria, and it is probable that some at least of the cases of malaria in infancy hitherto attributed to post-natal infection were in reality acquired in utero or at birth. Since malaria is common in pregnancy, while transplacental infection is rare, it is rational to suppose that congenital malaria may depend on some abnormality or accident of delivery. Dr. Forbes's case occurred in an infant aged 7 weeks, who had been born at term after normal labour. She had six febrile attacks before the periodicity was fully appreciated, and the parents, who had been born in Greece, were questioned as to a history of malaria. The mother then stated that she had had an unusually severe quartan infection in Greece seven years previously, but asserted that she had been free of all symptoms before coming to the United States in 1916. Examination of the infant's blood at the time of the seventh attack showed large numbers of malarial plasmodia in all stages of the asexual life cycle. The spleen was palpable 2 cm. below the costal margin. The mother's blood at this time also showed quartan parasites, but her spleen was not palpable. Under treatment with quinine hydrochloride in doses of 2 gr., at first every four hours for four days, then three times daily for four days, and lastly three times a day on each of two days of each week for two months, the splenic enlargement subsided, the child gained in weight, and at the age of 6 months had been free from any symptoms of malaria since treatment had begun. In a malarial community such a case would invariably be regarded as an instance of post-natal infection, but as the anopheles mosquito has not been found in Eastern Colorado, where the case occurred, congenital infection seems to be the most likely hypothesis.

"PINS AND NEEDLES."

PRICKING, tingling, "pins and needles," a feeling "like an electric battery," or, in more technical language, paræsthesia, is a subjective symptom of interest and occasionally of interpretative difficulty. Probably best regarded as similar to pain but not of sufficient intensity to be so classified, though its severity may sometimes raise it to the pain level, paræsthesia is characterised rather by a diffuseness and complexity and often by a background of numbness which suffice to distinguish it clinically from the sensation of pain. In the simplest instances the phenomenon is caused by a milder stimulus than that occasioning pain; when the ulnar nerve is pressed on at the elbow tingling results, whereas a knock on it will produce pain; if one leg is crossed over the other, if the edge of a chair exerts pressure on the back of the thigh, tingling ensues in the peripheral distribution of the sciatic nerve, and the segment of the limb is often said to be "asleep" or to have "gone to sleep." Evidently, then, in such commonplace examples of the symptom we cannot be sure that the pressure exerted on the nerve trunk is not simultaneously interfering with the circulation through the arterial vasa nervorum of the peripheral nerve or through its venæ comites. For the interpretation of the clinical phenomena we believe this question of concomitant disturbance of nerve-trunk circulation to be of the first importance. One of the ordinary types of minor complaint, as seen in the out-patient department of a large hospital, is acroparæsthesia, a condition occurring with much greater frequency in women than in men and recognisable by its appearance in elderly hard-working people whose hands are often lined and cracked by scrubbing and cleaning and frequent immersion in water; during the working hours little is noticed, but as the hours of rest and sleep come on intolerable "pins and needles" develop in the periphery of the upper limbs, effectually interfering with the onset of unconsciousness and forcing the sufferer to seek relief in constant movement and change of position. Such patients nearly always show early signs of arterial degeneration, and it is a feasible speculation to associate the acroparæsthesia with incipient arterio-sclerosis of the vasa nervorum, a relative ischæmia of the nerve trunks from insufficient general circulation; once circulation is established by the ordinary activities of the day the paræsthesia disappears. The seemingly little recognised condition of "venous neuralgia" is noteworthy for insufferable paræsthesiæ and has been shown by Edinger to be caused, in the case of the lower extremity, by a varicose state of the venæ comites of the sciatic nerve and to be curable by appropriate measures for venous support. Other instances of paræsthesia derived from certain implication of the circulatory element will readily occur to the clinician. Thus the whole vast group of the vaso-motor neuroses—Raynaud's syndrome, acroasphyxia, acrodynia, erythromelalgia, perhaps also causalgia—constitutes a class in which pain or paræsthesia, or both, cannot be separated in pathogenesis from symptoms definitely of vascular origin; nor in this connexion should intermittent claudication be forgotten. Again, paræsthesia is the usual accompaniment of any variety of neural infection, whether it amount to a structural neuritis or merely to a toxic state without objective signs. In any infective process invading the peripheral nervous system we cannot differentiate lymphogenous, hæmatogenous, or neural (parenchymatous) factors except by pathological investigation; clinically we do not know to which of these to assign the paræsthesia of which complaint may be made. General blood states, for example, pernicious anæmia, often induce peripheral paræsthesiæ; in the case of the disease known as subacute combined degeneration of the spinal cord both neural and circulatory elements may be at fault.

---

[1] American Journal of Diseases of Children, February, 1923.

Study of the subject, then, indicates the complexity of the pathogenic process in so banal a complaint as "pins and needles"; we are to suppose that pressure, or circulatory disorder (arterial, venous, or lymphatic), or infection or toxi-infection (neuronal or vascular) in some fashion impairs neural conductivity; the result in consciousness is a state of numbness or of paræsthesia, or of both simultaneously, referred by the brain to the periphery of the particular nerve distribution involved. For the unravelling of any unusual case, therefore, due attention must be given to a variety of considerations, and detailed information obtained as to the behaviour of the symptoms under a variety of conditions.

A REVIEW OF X RAY THERAPY.

Dr. Otto Strauss of Berlin has recently reviewed[1] the present-day position of the treatment of carcinoma with X rays. He traces the changes of ideas from those held during the early days of the application of X rays for the cure of malignant disease to our present-day conceptions and practice. At first it was generally believed that carcinoma cells could be destroyed by a strong dose of X rays, and that if it were possible technically to bring this dose to bear upon the deep-lying malignant tissue, all carcinomata would be within the range of cure. The whole question was thought to be well on the way of being settled, the only accessories necessary being the proper X ray tubes for giving the high dosage required. These were obtained, but the problem was then found to be complicated by the fact that the strong doses necessary to kill the carcinoma cells had a deleterious effect on the overlying normal tissues. This difficulty being overcome by the use of filters, carcinoma was promptly labelled a curable disease, the high dose being called the "carcinoma dose." Disappointment soon came, not altogether unexpectedly, for it was discovered that the hitherto unquestioned hypothesis of the uniform susceptibility of all carcinomata to X rays had not a shred of evidence to support it. The "carcinoma dose" disappeared, the high doses were diminished, and the view that small doses had a stimulating effect on carcinomata passed out of fashion as a grandmother's tale. It was decided that it was impossible to lay down the dose for any particular form of carcinoma. It was, however, found in practice that a great number of carcinoma uteri cases reacted regularly to a certain dose, and this dose has since been called the "carcinoma dose," recognising that the term has only a rough value. Although it has subsequently been found that other problems of an intricate and difficult nature are still to be solved, it must not be forgotten that real advance has only been made since a definite idea of a "carcinoma dose" has been fixed. In close connexion with the overthrow of the old "carcinoma dose" came a demand for a reduction in the strength of the dose. The reason for this was the observation that large doses were injurious to the natural resistances of the body. In course of time a certain conception of this "natural resistance" has been formulated, although in reality very little is known about it, and there has been much discussion about the spontaneous healing of carcinomata.

At this stage it was thought that the effect of the X rays was not on the carcinoma cells themselves, but rather on the surrounding connective-tissue cells, which were stimulated to activity and to proliferation so that they crushed the neoplasm out of existence. The connective tissue has come more and more to the forefront of the discussion. It used to be regarded as a by-product without much effect on the organism as a whole, but now it has been demonstrated that 16 per cent. of the adult body-weight is connective tissue, and that in no situation does a parenchymatous cell abut on a blood-vessel without a layer of connective tissue between. Further, since the importance of this tissue has been recognised as a water depôt, and a storing place for chlorides and fat, and since its significance has been pointed out for the maintenance of the H.OH group and for the formation of acids, our conception of its value has completely altered. In fact, connective tissue is an organ and must be treated as such. Experiments were now carried out to test the effects of the X rays on the connective-tissue cells, with the result that it was found that if with a certain dose they were stimulated to proliferate, their staining properties, chiefly of the so-called pyrrhol cells, were also enhanced. It was further observed, by means of their staining reactions, that there was a difference between the effect of the X rays on connective tissue and on parenchymatous tissue. Certain epithelial cells reacted three times more rapidly to the X rays than did connective tissue, so that by the time the latter had been stimulated, the former had already received an over-dose, and had begun to show signs of degeneration. Thus if less than such a dose was given, neither a degeneration of carcinoma cells was produced, nor was the connective tissue stimulated to destroy them; in fact, the carcinoma cells were rather stimulated to greater activity, and herein lay the danger of weak doses. In contrast to these observations Aschoff[2] showed that the effect of X rays was on the carcinoma cells themselves, and produced vacuolation of the protoplasm with alterations in and dissolution of the nucleus. A true metaplasia could also be produced. Strauss[3] too pointed out that if it were true that the chief effect of X rays was on the connective tissue, it would be expected that carcinomata of the scirrhus type would benefit most, but such has not been shown to be the case. Scirrhus carcinomata react badly to X rays. The action of the connective tissue has probably been overestimated, and if it were the chief factor in healing, spontaneous cure should occur much more frequently.

The view has been brought forward that large doses are injurious to the endocrine glands and as an explanation of the fact that X ray treatment has so little effect on carcinomata in the gastric region and in the head and neck, it has been suggested that large endocrine glands such as the spleen, pancreas, and suprarenals in the stomach region, and the parathyroids, thymus, and pituitary in the head and neck, come under the direct action of the rays and are so damaged that the general resistance of the body is lowered rather than raised. The case of the uterus is quite different, for in this region no large endocrine organs come under the rays, and it is well known that in the uterus the greatest benefit is obtained from the treatment. But how is the fact to be explained that carcinomata of the rectum do not react so favourably although there is equally no endocrine substance in the path of the rays? Among all the reasons given for a reduction in the dose of X rays, none seem to Strauss to be really substantiated, and he recommends the application of the large so-called "carcinoma dose." But he recognises that the question of dosage is very different when we are dealing, not with the primary tumour, but with post-operative prophylaxis. In the former we are aiming at the local destruction of the tumour, but in the latter, apart from any small recurrences to be dealt with locally, we are seeking to increase the general resistance of the body. Whether it is or is not possible to obtain such a result is very questionable, for we must honestly admit that about carcinoma immunity we know practically nothing. The power, once so much under discussion, which the normal serum possesses of destroying carcinoma, and which is absent from the serum of those suffering from carcinoma, has not been definitely demonstrated, nor does the discovery of a specific destructive ferment for carcinoma-protein bring us much nearer to the goal. Some experiments carried out by Caspari[4] are suggestive. He found that if animals were inoculated with carcinoma cells after exposing them to the X rays, they were immune; that if they were treated with X rays before and after inoculation, the carcinoma grew, but only feebly; and that if they were X rayed only after the inoculation, the tumour grew and was even stimulated by the application. The explanation given was that a leucocytosis was produced by the X rays with subsequent cell destruction, whereby a hormone was poured out in the blood, rendering it immune. Leucocytosis would therefore seem to be important for increasing the immunity, but what sort of hormone is set free is for the moment beyond our power of ascertaining. Strauss thinks that it is certainly not produced from the connective-tissue cells, but is probably derived from the endocrine organs. It is necessary, therefore, in post-operative X ray therapy to seek to produce a leucocytosis, and it is well known that this can be achieved. It is also known that too large a dose will produce a leucopenia, while small doses, after a preliminary drop in the number of leucocytes, produce an increase.

[3] Deut. med. Wochenschr., 1922, Nos. 12 and 13.

Strauss comes to the conclusion that the dosage necessary for the treatment of a primary tumour and that necessary after operation must be quite different, and that up till now the mistake has been made of trying to combine two different aims under one rule. Whereas strong doses are necessary for the former condition, much weaker ones are needed to stimulate the resistances of the body, and he thinks it is probably the quality rather than the quantity of the dose that will have to be altered, before successful results will be obtained. He suggests that rays other than the hardest, such as are used for the removal of tumours, might be employed to produce post-operative immunity.

PIONEERS IN LUNG SURGERY.

In an article which appears in the present issue Dr. C. Riviere and Mr. W. H. C. Romanis give an account of the directions in which surgery is being invoked in the treatment of pulmonary tuberculosis, recalling the words of James Carson, of Liverpool, who, just over one hundred years ago, envisaged the cure of pulmonary tuberculosis by surgical operation. Last week Dr. J. J. Perkins and Dr. L. S. T. Burrell indicated the application of artificial pneumothorax to conditions other than tubercle. A fortnight ago we printed an obituary notice of Prof. Chr. Saugman, whose introduction of the manometer into the technique of artificial pneumothorax established this method as one of acknowledged value and safety. We have now to record the death of another pioneer, Dr. Lucius Spengler, of Davos, who was among the first to use Brauer's method of incising the soft tissues down to the pleura before insufflating gas with a blunt cannula. All the resources of the Schatzalp Sanatorium, and of a large private practice outside, enabled Spengler to accumulate a vast amount of information regarding the successes and the limitations of collapse therapy, and his experience is revealed in a series of exhaustive papers by Ludolf Brauer and himself which appeared about the year 1910 in the *Beiträge zur Klinik der Tuberkulose.* Spengler did not stop at blowing gas into the pleura, but, in the considerable proportion of cases where adhesions hinder effective collapse of the lung, he supplied a large part of the clinical material on which other methods such as thoracoplasty and decortication or pneumolysis were carried out, many of them at Davos, others in the Surgical Clinic at Zurich University which was then in Sauerbruch's charge. Spengler was widely known for his mature clinical judgment and his faculty of grasping the essential elements in the lives of his phthisical patients. The treatment of tuberculosis at Davos owes much to his life work, for he was one of the two sons of Dr. Alexander Spengler, the local practitioner in the Davos valley, who first called attention to the value of the alpine climate about 60 years ago.

DISABILITIES OF SCHOOL AGE RESULTING FROM RICKETS.

The crippling of school-children even in rural areas as a result of rickets occurring in early life is attracting the attention of county health authorities. Dr. H. P. Newsholme in his annual report as school medical officer to the North Riding of Yorkshire County Council details the results of an inquiry made during 1922 into the prevalence of rickety deformities and their effect on the capacity for education. The children were unselected except in regard to age; the majority were in the age-groups 5–6, 8–9, and 12–13 years, and 6566 boys and 6224 girls were examined. The deformities noted were classified into beading of the ribs, enlargement of the ends of long bones, bossing of the forehead, gross deformity of the chest, knock-knee, bow-leg, and deformity of the spine. One or more of these deformities was present in 3·9 per cent. of the boys and 1·7 per cent. of the girls—an average of about 3 per cent., the large excess in boys being almost wholly under the headings of beading of the ribs and deformity of the chest. Knock-knee, bow-leg, or spinal deformity was found in 0·7 per cent. of the children. These evidences of past rickets were not regarded as a measure of the prevalence of that disease, but only as an indication of the number severely affected. In 2934 instances inquiry was made of the parents as to whether any child in the family was known to have had rickets, with the following result: in the larger towns such a history was obtained in 7·5 per cent. of 1658 families, in the country towns in 6·5 per cent. of 553 families, and in the rural areas in 4·4 per cent. of 723 families, an average of 6·5 per cent. Dr. Newsholme thinks it would be unreasonable to imagine that the 3 per cent. of children of school age, showing deformities due to past rickets, were derived from a mere 6½ per cent. of cases of rickets in the child population. He concludes that the parents understated its prevalence in their families, not knowing that some ill-defined malady through which the child had passed was in fact rickets; and he thinks there is need of a general education of the public in the matter.

With remarkable uniformity the children of either sex who showed deformities due to rickets were found to be not so tall and not so heavy as the average for their age, this poorer physique continuing manifest throughout the whole of school life. Thus among 1986 boys of 8 years examined, those with evidence of past rickets were on an average 1·9 inches less in height and 4·3 lb. less in weight than those without rickety deformity. This harmful influence of rickets on physique is well known, but the association of rickets with educational retardation is not so generally recognised, and this is perhaps the most interesting of the observations in this inquiry. It was found that children showing the deformities specified were definitely backward in their education, and continued backward throughout school life when comparison was made with the average attainment of the children as a whole under the same general conditions. For example, among 8-year-old boys 44 per cent. of those with signs of rickets were below the second standard, as compared with only 30 per cent. of the boys as a whole. It is suggested that this result may be due in part to faults in the home environment and in part to direct damage produced by rickets. Such children are drawn largely from families in which there is less parental interest and less capacity for domestic management than in the population at large. At the same time a susceptibility to catarrhal conditions, induced by rickets, may interfere with education, partly by causing irregular attendance and partly by sapping the child's general vitality. Dr. Newsholme concludes his report by remarking that rickets is to be prevented on the one hand by educating parents as to diet and food values and as to the part played by sunlight, fresh air, and exercise; on the other, by improving the home environment in regard to overcrowding and structural defects which obstruct ventilation and lighting in the house. He calls for coördination in the efforts of the public bodies concerned, the Public Health Committee with its child welfare centres and health visitors, the Education Committee with its nurses and schools of cookery and household management, and the Poor-law medical authority with its powers of supplying food in necessitous cases.

A CONTROL FOR THE AUTO-URINE REACTION.

The question whether it is possible by any means to demonstrate the existence of an active tuberculous focus in the organism has long been the subject of debate. Prof. H. Wildbolz answered it in the affirmative. Many observers dispute the practical utility of the reaction described by him. Wildbolz asserted that when the urine of a tuberculous patient, concentrated to one-tenth, is injected intracutaneously, a circumscribed infiltration ensues showing the existence of an active focus. This reaction was said to be due to the elimination by the urine of tuberculous antigen, and Wildbolz contested that besides tuberculosis only certain kidney conditions and staphylococcæmia gave positive reactions. He made a proviso, therefore, that the test was useful only in individuals who gave a positive von Pirquet reaction. Dr. Mario Venuti has taken up the question,[1] adopting a system of controls. The objections to the validity of the reaction may be summed up as follows: The infiltration even when pronounced may not be an indication of a specific reaction since it occurs in healthy subjects, and may be attributable to urinary salts, toxicity of the urine, or hypersensibility of the skin. On the other hand, the reaction may be negative in individuals who have evident and active tuberculous lesions and react to tuberculin. The controls proposed by Dr. Venuti consist in injecting into the individuals under examination, not only their own urine, but also the concentrated product of one from a certainly healthy subject, and from another who is the proved subject of tuberculosis in a marked degree. In practice three events may occur. The patient under examination may react neither to his own nor to the physiological urine. This absence of infiltration may be the index either of a negative reaction in consequence of the absence of antigen in the urine, or of no reaction, dependent on anergy in the subject. If the first hypothesis is correct the hetero-urine reaction with urine from another tuberculous individual constituting the control will cause in the patient a characteristic positive result, and the evident absence of antigen in the auto-urine excludes the presence of an active tuberculous lesion. If, on the other hand, it is a case of anergy not even the urine of the control will be sufficient to cause infiltration, and it will be necessary to inject the urine under examination into the control to confirm or exclude, according as the reaction is positive or negative in him, the activity of the tuberculous process in the patient under examination. In the second place, when the patient gives a positive reaction to his own and a negative to physiological urine, in order to prove the specificity of the reaction and exclude the intervention of some unknown aspecific factor to which the subject is sensitive, it will be useful to inject into the control the urine under examination and that of the control into the subject. If both are equally positive then the subject is allergic and affected with active tubercle. A third possibility is that the patient may react positively both to his own and to physiological urine; his skin is evidently hypersensitive to urinary salts, and the injection of the urine of the control confirms it. Here, as in the first case postulated, the injection of the urine under examination into the control will show antigenuria and hence active tubercle. Dr. Venuti insists strongly on the value of these controls without which he considers Wildbolz's reaction has no diagnostic importance. If the controls are used in the manner described he claims that the combined results may be used as a sure test as to whether an active process is present.

THE APPEAL FROM THE NEAR EAST.

In our present issue we publish an account by Sir Patrick Hehir, medical adviser to the British Red Cross in Greece, of what is being done for the million refugees from Smyrna, Armenia, Syria, and Thrace who are now scattered throughout that country. Those who served with the Allied Expeditionary Force at Salonika will be interested to learn that their old camps and hospitals have provided valuable shelter for many homeless people. The most necessary measures among the refugees are the isolation of cases of infectious diseases and the prevention of the spread of the latter. Antityphus inoculation is being carried out on a voluntary basis. The medical representatives of the League of Nations are actually inoculating all refugees in Greece against enteric, paratyphoid A and B, and cholera, and are also vaccinating them against small-pox. Sir Patrick Hehir speaks highly of the efforts of the Greek Government and the wealthier classes of the community on behalf of the refugees. In cordially seconding his appeal for support from the British people, we may refer to the excellent All-British Appeal cinema film shown to press representatives on March 14th at the West End Cinema, which depicts relief work in Greece, and should be of value in making clear the need of generosity in the Near East.

PITYRIASIS RUBRA PILARIS.

Dr. Erwin P. Zeisler,[1] dermatologist to the Cook County Hospital, Chicago, has now recorded the first instance in the United States of the familial occurrence of pityriasis rubra pilaris, although two cases of the kind had been previously reported by French and German observers (Beurmann in 1910 and Gaertner in 1921). Dr. Zeisler's patients were a man, aged 46, who had had the disease since early childhood, and three of his four children—viz., a boy aged 12, and two girls aged 16 and 14—who all developed the disease during the first year of life. The father showed a branny erythroderma of the scalp with involvement of the ears. The face, chest, and back were entirely free. There were scaly, rough plaques, chiefly on the extensor surface of the arms around the elbows, and characteristic black plugs on the dorsal aspect of the metacarpus and phalanges. On the lower extremities were oblong, red, scaly patches over the knees and on both sides of the calves. The palms and soles showed a diffuse thickening with transverse striations of the nails. There were no subjective symptoms. In the three children the eruption presented the following appearances: The scalp showed a diffuse redness with branny desquamation. On the cheeks, forehead, nose, and ears there was a shiny seborrhœic type of inflammation with exaggeration of the lines of the skin. On palpation the skin was thickened, inelastic, and rougher than normal. At the lower border of the neck the erythroderma terminated abruptly. Apart from a few scaly lesions on the upper part of the chest, the trunk was free. The arms presented scaly, greyish-red, psoriasiform plaques, chiefly affecting the extensor surface near the elbows. The wrists and backs of the hands showed erythrodermic patches made up of conical papules. Only one case presented the black punctiform plugs characteristic of the disease—on the wrists and, to a lesser extent, on the phalanges. On the lower limbs there were confluent scaly patches with islands of normal skin intervening. On the legs below the knees and on the dorsum of the feet the scaling and roughness were more marked and suggested ichthyosis. The soles showed a diffuse keratosis. In the children, as in the father, there was a striking absence of subjective symptoms. The patients were kept under observation for several years and always showed spontaneous improvement in the summer months. Although only one of Dr. Zeisler's patients showed definite evidence of hypothyroidism, the improvement of the skin condition under thyroid administration was very striking in all, as in other recorded cases of pityriasis rubra pilaris. Locally the free use of baths, followed by a mild emollient such as benzoated lard or lanolin, proved more effective than stronger keratolytic or reducing agents. Dr. Zeisler found that the disease improved up to a certain point under X ray treatment but became refractory to further röntgenisation.

THE IDIOSYNCRASIES IN THE DIAGNOSIS OF SKIN DISEASES.

In an address to the Sheffield Medico-Chirurgical Society Sir Norman Walker has recently pointed out that the skin, more than any other organ of the body, except, perhaps, the stomach, is subject to idiosyncrasy. Just as surgeons, he said, had idiosyncrasies in the way their skin reacted to antiseptic lotions, so people generally showed marked personal peculiarities of irritability to special varieties of soap. Other cases of dermatitis had been traced to feather boas cleaned with a certain form of flaked soap, or furs cleaned with formalin. In regard to occupation it was important to find out exactly what a man was doing when he presented himself as a skin patient. A patient who said he was a "telegraphist" was found to be a cleaner of instruments for which he used turpentine. Certain woods, notably teak and satin-wood, were liable to cause irritation in some persons; various plants, such as the *Primula obconica* and *Rhus toxicodendron*, in others. Cosmetics, hair dyes, and quack ointments were also frequent offenders. In his student days, Sir Norman Walker said, dermatology had reached the stage of observation and collection of facts. Bacteriology was then in its infancy. Many diseases then attributed to "gouty" or "nervous" conditions were now attributed to definite organisms. The method of inquiry was important. The patient should be encouraged to tell his own story. Questions should be put in such a way that it was equally easy for him to answer "Yes" or "No." Sir Norman Walker was optimistic as to the possibility of elucidating even subtle and apparently mysterious causes by careful inquiry; as a text for his address he chose from the Book of Job the text "The cause that I knew not I searched out."

ADRENAL INSUFFICIENCY IN EXPERIMENTAL ANIMALS.

It is known that removal of both adrenal glands is accompanied by a steady rise in the number of red corpuscles per c.mm. of blood, a concentration of the blood and a greatly increased susceptibility to histamine. In the current number of the *Journal of Physiology*, Dr. C. H. Kellaway, records observations made on adult cats, the medulla of the glands being destroyed by radium emanation, from a sealed capillary glass tube placed in the gland. The amount of medulla remaining at different periods during life was determined by the degree of paradoxical pupil dilatation produced by anoxæmia and by injecting histamine. It was shown that animals can survive in apparently good health for many months in the absence of nearly all the intra-medullary chromaffin tissue. The destruction of sufficient cortex appears to cause symptoms of acute insufficiency while some of the medulla is still functioning. There is very little in common between the symptoms of Addison's disease and the picture presented by animals dying rapidly of adrenal insufficiency, apart from lowered blood pressure and muscular weakness which appear in both. The symptoms which appear in animals which survive in good health for long periods after destruction of most of their intra-medullary chromaffin tissue are not very striking—the most notable change being a fall in the temperature of the animals. A subcutaneous injection of 0·5 mg. of adrenalin restores the animal for a time to its normal preoperative condition. Another symptom, observed in two animals only, was development of dark-brown patches of pigment in areas of the skin which had been shaved. No pigmentation of mucous membrane was observed. In chronic insufficiency of both cortex and medulla, terminating in death, the symptoms resemble more closely those occurring in acute experimental insufficiency than those met with in Addison's disease. The rise in hæmoglobin is an early and valuable sign of insufficiency. Histamine causes increased output of adrenalin and the effect is in part a direct one on the adrenals. The concentration of the blood in animals dying of adrenal insufficiency is due to cortical effect, while the altered concentration reaction to small doses of histamine in such animals is due to medullary defect. Both cortical and medullary defect appear to play a part in the "collapse" type of response to the injection of small doses of histamine. The subcutaneous injection of adrenalin antagonises the action of histamine in causing concentration of the blood. It also masks the hyper-sensitiveness to histamine exhibited by animals with insufficiency.

SHOULD ABORTION BE INDUCED FOR TUBERCULOSIS?

It is disappointing that so little is known of the relation of tuberculosis to pregnancy. The most important work ever undertaken in this field is probably that published in 1917 by Prof. Forssner, of Stockholm, and abstracted at some length in *Tubercle* for August, 1920. Two recent publications on this subject not only show that Forssner's investigations have failed to receive the attention they deserve, but they also prove that two eminent authorities, one a German, the other a Frenchman, may still hold diametrically opposite views with regard to the induction of abortion. Prof. Winter,[1] of Königsberg, considers that slight and inactive pulmonary tuberculosis does not warrant this course, but it is indicated when the disease is progressive. Fever he considers a clear call for abortion, and even when there is no fever he thinks that the disease may yet be progressive, in which case abortion is indicated. He refers to 14 cases, in seven of which the refusal to induce abortion was followed by progress of the disease, and with these and similar experiences he takes the attitude that clinical signs of progressive tuberculosis are, with very few exceptions, an imperative indication for interrupting pregnancy. The second paper, by Prof. L. Bernard,[2] is a defence of conservative measures. His statistics are singularly instructive. Of 327 tuberculous women attending his hospital, 81 had recently been pregnant. In other words, in about 24 per cent. the disease had begun during, or had been aggravated by, pregnancy and its sequels. Of the recent cases of tuberculosis, there were 22 in which the disease had broken out before, and 33 after, confinement. Among the cases in which old disease had been aggravated, there were 15 in which this aggravation occurred before, and 11 after, confinement. These figures seem to suggest that while pregnancy chiefly affects old-standing disease, the outbreak of recent disease is chiefly determined by post-partum influences. By themselves these figures give pregnancy and its sequels a most sinister reputation, and they might suggest the interruption of pregnancy at all costs. But among Prof. Bernard's 327 cases there were also 85 tuberculous patients whose pregnancies had apparently not affected their disease. These figures are well worth pondering over when the induction of abortion is discussed, and an attempt is made to ask in each case: (1) Is the mother greatly endangered? (2) Is the danger definitely due to the pregnancy? and (3) Will the danger cease with the cessation of pregnancy? As no one can give a definite answer in the affirmative to all three questions, Prof. Bernard has assuredly taken up a strong position in refusing to induce abortion even in cases of progressive pulmonary tuberculosis, and it has yet to be proved that the effects of induced abortion are less injurious to the tuberculous woman than letting pregnancy proceed to term.

LIVERPOOL GUARDIANS AND THE TREATMENT OF CANCER.

At their meeting on Feb. 28th the West Derby Board of Guardians—now the Poor-law authority for the whole of Liverpool—had for consideration a proposal to set aside for a period of two years Dingle Mount, one of their smaller institutions containing 50 beds, for research work in connexion with the treatment of cancer. The scheme was the outcome of certain encouraging results of the work of Prof. Blair Bell on "The Influence of Saturnine Compounds on Cell Growth," which was published in The Lancet of Nov. 11th, 1922. Thess results had been brought before the guardians by a strong committee, including Dr. J. G. Adami, Vice-Chancellor of the University, Prof. F. T. Paul, and Sir Robert Jones. There was considerable criticism of the scheme, some notably ill-informed and some offensive, and after prolonged discussion it was rejected by 42 votes to 24. Since the meeting of the guardians a letter has appeared in the *Liverpool Daily Post* over the signature of the three members of the committee mentioned above deprecating the personal attacks made upon Prof. Blair Bell and exposing the more flagrant of the arguments of the opponents of the scheme.

As our readers are aware, Prof. Blair Bell has for several years been testing the activity of certain combinations of lead upon neoplastic cells. He has been extremely guarded in his deductions, desiring that no false hopes should be raised or any public pronouncement made till all the evidence has been thoroughly sifted by experts in the various branches of the work, and the lapse of time shall have set its seal upon such results as he may obtain. To the influential committee before whom the whole of the facts have been placed, these results appeared sufficiently encouraging to demand the most careful and extended investigation. A suggestion was therefore put forward to assign Dingle Mount for the treatment of cases of cancer already in Poor-law institutions along the lines suggested by Prof. Blair Bell. Results were to be watched by the consultative committee, and the clinical and laboratory work assisted by a staff consisting of Dr. John Hay (medicine), Mr. H. F. Woolfenden (surgery), Prof. E. E. Glynn (pathology), Prof. W. C. McC. Lewis (physical chemistry), Dr. W. J. Dilling (pharmacology), and Dr. H. E. Annett (comparative medicine). As regards expense, the patients, of course, would be chiefly those for whom the authorities had already undertaken responsibility; and in order to cope with the additional expenditure essential for the experimental and laboratory side of the investigation a large sum of money has been definitely guaranteed by the generosity of a small band of Liverpool business men. No additional cost therefore to the ratepayers was anticipated.

These points were laid before the board of guardians by a deputation headed by Dr. Adami. The Ministry of Health was approached by the guardians for an opinion and declared in favour of such work being undertaken, provided that no fresh charges were incurred by the ratepayers. Unfortunately, the board of guardians have not only taken upon themselves to reject the scheme, but have allowed at their meeting criticisms of Prof. Blair Bell's motives and of the scientific quality of the work. It is to be hoped that such an opening as this, in connexion with so important a matter as cancer, concerning which we can ill afford to let slip any chance of progress, may yet be utilised.

THE OUTBREAK OF SMALL-POX IN DERBYSHIRE.

A local correspondent writes, under date March 11th, as follows: "The prevalence of small-pox in several parts of Derbyshire has made the population realise the necessity of vaccination. The epidemic seems to be of some duration. The first cases appeared as much as five months ago, but they were mild cases and their occurrence caused little attention outside medical circles. Now, however, the cases are more virulent as well as growing in number. At Clowne, which has scarcely more than 6000 inhabitants, during the first ten days of March there were 11 new cases of small-pox; the total for Derbyshire is now 69. The rural council has issued notices to the inhabitants that the law will be put into action if they do not at once notify, or if they attempt to conceal cases. The schools are not closed, only contacts are forbidden to attend. But these contacts have been attending Sunday schools, and this has caused some complaints to be made and more drastic precautions are now likely to be enforced. The important towns of Chesterfield and Mansfield, to say nothing of the great city of Sheffield, are close at hand; constant intercourse takes place with these centres, and it is quite certain that at first some cases of small-pox were not notified. Drastic measures were therefore very necessary, and the visit of Dr. Wilkinson, representing the Ministry of Health, has had a good effect in impressing the ratepayers with the fact that effective precautions are the truest form of economy. The proposal to isolate contacts as well as patients caused some alarm, especially when the cost of such a measure was considered. So, for the moment at least, it was not adopted; Dr. Wilkinson has been content to insist that all the contacts should be at once vaccinated. But people persist in calling on neighbours where there is small-pox to express sympathy. Complaints have been made against such forms of mistaken kindness, notably at a recent meeting of the Alfreton Urban Council. That, in spite of this, the necessity of precautions is better realised has just been enforced in a rather peculiar manner. The Bolsover Colliery Prize Band, seeking to make good use of their popularity, asked the Eckington justices to grant them a licence to give a concert at the Clowne picture-house. The chairman, Colonel Butler Bowdon, immediately inquired whether all the members of the band had been vaccinated. No one present was prepared to vouch for the vaccination of the musicians, and thereupon the chairman declared that, in consequence of the small-pox epidemic prevailing at Clowne, he did not think it advisable to grant the licence, and the application was refused."

We shall be interested to hear if this action becomes a precedent, so that henceforth public performers will be called upon to produce vaccination certificates.

Hospitals in the County of London or within nine miles of Charing Cross desiring to participate in the grants made by King Edward's Hospital Fund for London for the year 1923 must make application before March 31st to the Honorary Secretaries, 7, Walbrook, London, E.C. 4. The nearness of this date should be borne in mind. Applications will also be considered from convalescent homes which are situated within the above boundaries or which, being situated outside, take a large proportion of patients from London.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XI.

TREATMENT OF INGUINAL HERNIA IN CHILDHOOD.

IN infancy, inguinal hernia is much more common in boys than girls, and it is often associated with congenital constriction of the external urinary meatus and with phimosis; the first step in treatment should be the cure of these conditions and the relief of any other cause of strain, such as constipation and bronchitis. Narrowing of the meatus is often associated with phimosis; in all operations of circumcision the meatus should be examined and if necessary enlarged by a ventral cut. One side is then puckered by a fine catgut stitch to prevent adhesion of the raw surfaces and recurrence of the disability. There is no evidence to support the idea that screaming in a boy baby is likely to cause hernia and justifies irregular feeding or other means of pacification; the best way to train babies of both sexes not to scream is to ignore them. If, however, a hernia has already developed, or there is mal-descent of the testicle, prolonged screaming calls for inspection of the baby; descent of hernial contents or torsion of the testicle may have occurred and necessitate treatment, such as readjustment of a truss.

Hernia in Infants.

Conservative Treatment.—In uncomplicated cases, seen during the first nine months of life, inguinal hernia may be treated satisfactorily by trusses. For most babies a wool truss is efficient, cleanly, easily looked after, and cheap; it may be made of several strands of soft knitting wool, or of a strip of flannel. For each case several trusses should be available, so that the patient may never be without one even for a few minutes; the mother or nurse is instructed that as soon as the baby is quiet after the removal of a soiled napkin or after the bath the wet truss is to be removed and a fresh one applied, when the skin has been dried and powdered; while this is being done, in many cases the hernia can be prevented from descending by keeping the hips extended; failing this, finger pressure on the inguinal regions must be applied until the truss is in position. For fat babies, even under 9 months, a wool truss is difficult or impossible to fit, and a pneumatic rubber horseshoe truss must be used; it should fit snugly each side of the base of the penis, and the perineal straps must be firmly adjusted; wool should not be interposed between truss and skin, for it encourages moisture and inflammation. Special care should be directed to the skin, and a second truss be available so that there shall be no intermission in treatment.

Radical Cure.—For herniæ presenting special difficulty in reduction or retention cure by operation is occasionally advisable even in the first nine months of life. Marked wasting and bronchitis are contra-indications to operation, but chronic digestive disturbances form no bar, for they are often due to the presence of the rupture. Radical cure of hernia in infants, as in older children, is a simple operation. The cord at the external abdominal ring is exposed through a short incision; the sac is opened and dissected up to its neck, care being taken not to grasp the delicate vas with forceps; the sac is then removed after transfixion and ligature of its neck, one stitch is placed in the coverings of the cord, and the skin wound is closed, preferably with a subcuticular suture; the object of using this form of suture is its ease of removal. During after-treatment the baby is kept on his back, with the elbows splinted in extension, and the wound will be most easily kept dry and clean if no dressing is applied. Operation in these very young babies should be reserved for cases of special difficulty, for, besides the possible interference with breast-feeding, there are special risks from the effects of anæsthetics, and very careful nursing is required.

Hernia in Young Children.

Conservative treatment after the age of 9 months consists in the application of a horseshoe rubber truss; these trusses are adjustable, but the rubber stretches before long, and new trusses must be supplied about every four months. This method is suitable to infants up to 15 months; after this time the most suitable truss is a light rubber-covered spring one, carefully fitted. If by these methods the hernia is kept unintermittently reduced, in many cases cure may be expected by the time the child is 2 years old; if, however, the rupture is present after the fifteenth month, cure by truss is unlikely, and the simple operation mentioned above is to be advised, in the absence of rickets or other special contra-indication.

Strangulation is predisposed to by constipation and bronchitis and is not uncommon in babies; it is rarely dangerous, and can usually be overcome without operation. The baby should be placed on his back with the legs tied in a vertical position and the buttocks raised on a pillow; a fomentation is applied to the inguinal regions and scrotum. In most cases after half-an-hour either it will be found that the contents of the sac have slipped back, or reduction can be effected by light manipulation. Failing this, operation must be undertaken.

Operation is the most suitable method of treatment for cases of hernia seen after infancy; the objections to treatment by trusses, especially its interference with athletics, are sufficiently obvious in children of school age. Simple removal of the sac with ligature of its neck high up is all that is necessary, opening up the inguinal canal and suturing muscles being only called for in certain of the rarer forms of hernia, especially the interstitial varieties associated with retention of the testicle.

Hernia Complicated by Mal-descent of the Testicle.

Incomplete or delayed descent of the testicle is very common and is nearly always accompanied sooner or later by a congenital hernia. Though the condition is usually noticed early, the abnormal position of the testicle as a rule produces no symptoms and calls for no treatment in the earlier years of life. In some cases it is possible to limit the development of the hernia by the application of a truss with a forked pad; but no truss should be applied if there is risk of pressure, continual or occasional, on the testicle; apart from pain, this would tend to increase the probabillty of the testicle failing to function later. In cases of hernia associated with mal-descent of the testicle operation is best deferred until the boy is over 7 years of age; in some the testicle makes a late descent and simple cure of the hernia is all that is necessary. Torsion of the testicle, and strangulation of a hernia with incomplete descent of the testicle, are indications for immediate operation at any age, and in such cases the testicle must often be removed. The best operation for uncomplicated cases of combined mal-descent of the testicle and hernia is one allowing the testicle to be brought into the scrotum.

WITH THE GREEK REFUGEES: AN APPEAL.

By Sir Patrick Hehir, K.C.I.E., C.B., C.M.G.,
MAJOR-GENERAL, I.M.S. (RET.)

At the present moment there are about one million refugees in Greece, scattered over the country in smaller or larger groups. At the end of December there were 868,186; since then roughly 150,000 more have wandered in by ship and train, or in the north by cart or on foot. They have come from many regions—Smyrna, Armenia, Syria, Eastern Thrace, and areas bordering on the Black Sea; there are likewise among them some Assyrians. These people soon settle down, and are, as a rule, unwilling to move, except when they feel that they can do better in other camps, or have sufficient capital to start small shops, or find employment in their own trades.

The refugees have been chiefly housed in and near the larger towns. They are located in barracks, prisons, specially erected huts, offices and Government buildings of all kinds, in churches, synagogues, temples, mosques and theatres, cinema palaces and other places of amusement, warehouses, stores, factories, schools, stables, railway buildings, under canvas, in verandahs, along quays, and wherever shelter of any kind is available. In the Salonica area the old British, French, and Greek camps have provided shelter for many thousands at Harmankieu, Kalamaria, Lembet, and Toumba; the old British General Hospital Tarant huts in particular are accommodating large numbers of these unfortunate people. The huts required little repair; the water-supplies were again revived, and it is interesting to see familiar "Thresh" and "Velox" steam disinfectors again delousing infected clothes and bedding. In some places homes have been provided by the local inhabitants for the better-class refugees—for example, in Salonica, by the British and American residents. The age- and sex-distribution of refugees has varied greatly. Those from Asia Minor contain few men and boys of fighting age, since these were taken by the Turks as prisoners. The old men and women are in a low state; the mortality among them has been high. The refugees from Eastern Thrace are comparatively healthy; all got away deliberately and were able to bring with them much of their worldly goods.

Though there are several organisations carrying out relief work—the British Red Cross Society, the American Red Cross Society, the International Red Cross Association, the League of Nations, "Save the Children" Fund representatives, American Y.M.C.A., Near East Relief, and others—so far as I have been able to see there is little or no overlapping. Each is operating in a specific way over a more or less definite area. The task connected with refugee relief is altogether too vast for any one philanthropic body, and even with the wise division of labour existing it is probable that at least some of these organisations will cease to function for want of financial support.

The Organisation of the Camps.

On the whole the conditions are more satisfactory than I expected, although much misery, discomfort, and hardship is obvious in every refugee camp. The size of the camps varies from holding, say, 500 to 12,000. They are usually run on the following lines. A person of some importance, selected from among the refugees, acts as a sort of under-commandant, and, assisted by some soldiers, exercises discipline of a kind. The doctors are Greek refugees. The sanitary work connected with epidemic disease is being carried out by the Government Health Department under the guidance of an officer of one of the Red Cross societies. The vaccination against enteric, cholera, and small-pox is being done by a special establishment organised by Dr. Gauthier, delegate from the League of Nations. This work is very well done. Medicines are provided by the various relief associations, supplemented, when necessary, by supplies from the Greek Government medical stores, but as there is usually great delay in compliance with indents made on these stores, many of the drugs have to be purchased from chemists locally. The British Government made a valuable and timely gift in the shape of a large stock of medicines, medical and surgical equipment, and some hospital appliances. In some camps the water-supply is defective, which interferes with attempts to eradicate typhus fever from an infected camp. The Greek administration is making every possible effort to remove this difficulty.

Hospitals.—It cannot be said that the hospitals of the refugee camps are run on ideal lines. The medical officers are in almost all cases refugees themselves, and, though obviously doing their best, in their present depressed condition are wanting in initiative, organising ability, and power to exercise proper discipline; absence of discipline and order are the two great defects in these institutions at present. Housing conditions and general hardships, insufficient food and exposure, have considerably reduced the vitality of the refugees, so that when disease attacks them it runs a serious course and is frequently fatal. This high mortality has aroused antipathy to the hospitals; cases of sickness in the early stage are hidden, and often it is only when the patient is dangerously ill that hospital relief is sought. This is one of the ways in which typhus fever is being kept up. Many cases of serious illness are due to prolonged malnutrition; this is specially the case with children and infants, a fair proportion of whom are in a marasmic state. Enteritis is one of the commonest of the infant diseases in these camps, and the mortality from it is heavy. The debilitated mothers have either no milk or a scanty supply of poor quality. This is the time for firms manufacturing dried milk or infants' foods to come forward with help, despatching their supplies through the right channels.

The Activities of the British Red Cross.

In the Athens district the camp with which the British Red Cross is specially connected is in New Phaleron, and is known as Stringos Camp. It contains about 3500 refugees occupying a large vacated factory. The medical work is carried on by three refugee Greek doctors, and pro tanto is satisfactory. It has a small hospital of 30 beds, the serious cases being sent to one of the general hospitals in Athens; there are some 60 out-patients daily. As in all the Greek camps, the latrine arrangements are very foul; we expect a British medical officer here as superintendent, when these things will be on a more satisfactory footing. There are three British ladies doing excellent work as nurses and supervisors; more are required, and some are due in a few days' time. The British Red Cross Society is meeting the medical and sanitary needs of another smaller camp containing 350 refugees near Athens. The Society has likewise taken over Lady Rumbold's Hospital of 300 beds at Guimulgina. It hopes to open out smaller hospitals at Drama, Seres, Kavalla, and other areas in Western Thrace. A British Red Cross train laden with various supplies, including a valuable and much required stock of medicines, and provided with four ambulance coaches, is stabled at Salonica, whence it is distributing its contents.

Inoculation against typhus is being adopted; it is at present in the experimental stage, and is voluntary. There is absolutely no reaction. Dr. Georges Blanc, Directeur de l'Institut Pasteur Hellenique, tells me that he has done thousands of inoculations, has not heard of any inoculated person acquiring the disease, but cannot yet express an opinion as to its prophylactic value.

The most important measures necessary at the present time are the isolation of all cases of infectious disease and the prevention of the dissemination of such diseases. Cases of typhus fever are sometimes not discovered in refugee camps for a few days after they have become infective. I have seen at least a dozen cases diagnosed in the early stages as influenza ; one group of these wrongly diagnosed cases infected a whole general hospital. In a few instances I have discovered cases of typhus in the pre-eruptive stage walking about among the healthy members of camps. There seems to be a remarkable difference in the intensity and mortality of typhus in different areas. In the Athens and Salonica districts the disease is not so severe as in other places. In Corfu it is extremely virulent ; I have just heard that of 25 doctors employed with the typhus outbreak in that island in February eight have been infected and seven have died, but my informant is not a medical man.

The Work of the League of Nations.

The League of Nations is undertaking admirable work in connexion with the prevention of infectious disease and the permanent settlement of 10,000 refugees. Their medical representatives are now carrying out the enormous task of inoculating the whole of the refugees in Greece against enteric, paratyphoid A and B, and cholera, and vaccination against small-pox. These protective measures are being carried out at the same time ; a polyvalent vaccine of T.A.B. plus cholera vibrios is being injected, and ordinary vaccination against small-pox is done at the one sitting ; the polyvalent vaccine is, of course, repeated on the eighth day. The League of Nations is also engaged upon the permanent settlement of 10,000 refugees from Eastern Thrace, the Caucasus and elsewhere, on land granted by the Greek Government, some in towns, others in agricultural villages. The Lady Rumbold Hospital is connected with this movement ; all the adjacent villages will have visiting doctors, serious cases being transferred to the general hospital, or to smaller clearing hospitals, which will also be under the British Red Cross.

The work of relief being done is in no sense a permanent remedy. Nothing short of making the people self-supporting can be looked upon as a solution of the difficult problem that faces the Greek Government. Refugees cannot be made strong and fit for real hard work on relief rations. One of the most puzzling difficulties at present is the finding of suitable work for these unfortunate people. Many have got into the way of expecting gratuitous relief, and when work comes their way they move in the opposite direction. It may become necessary not only to provide work, but to compel the people to work. The manner in which the Greek Government and the better classes of the Greek community have worked on behalf of the refugees has aroused universal admiration. I believe that one of the happiest and best accommodated refugee camps is that of the Armenians in a suburb of Athens.

I would make an earnest appeal to the philanthropy of the people of our Empire to help in the cause in which I am personally engaged—the work of the British Red Cross Society. There are many Britishers, men and women, doing all that is in their power to look after the weaklings and sick among the refugees in the midst of typhus, small-pox, measles, and other infectious diseases. I can also vouch for the fact that all funds entrusted to the British Red Cross (Near East Section, 35, Albemarle-street, London) are devoted to the care of those for whom it is craved, and they are expended with the greatest possible judgment. At present the Americans are taking by far the largest share of this relief work in all its branches.

MEMORIAL TO THE LATE MR. HUGH WHITWELL.—It is proposed by several friends and patients of the late Mr. Hugh Whitwell to endow a cot in the Jenny Lind Hospital for Children, Norwich, as a memorial to him, the cot to bear his name. The cost is £1000, and a sum of about £700 has already been received towards this object.

ROYAL SUSSEX COUNTY HOSPITAL, BRIGHTON.

REPORT OF COMMITTEE OF INQUIRY.

THE report of the committee of inquiry appointed on Nov. 16th, 1922, to inquire into the general administration of the Royal Sussex County Hospital has now been issued,[1] and opens with an expression of regret that the board of management did not consult an expert at the beginning of 1922, when they found that their expenditure in 1921 greatly exceeded that of 1920, in spite of the fact that there had been a considerable fall in nearly all prices. The committee gave statistics showing that while the cost in a group of provincial hospitals fell £3 per bed in 1921, compared with 1920, the Royal Sussex County Hospital expenditure increased £15 per bed.

Observations on Expenditure.

Sir Napier Burnett, whose assistance was invited by the committee, found, in a report to that body, that under two heads of expenditure alone there was a very large excess over the average of comparable hospitals. Under the head of "domestic," the expenditure exceeded the group average by 32 per cent., or £72 14*s.* per bed, as against an average of £62 13*s.* per bed for the two years 1920 and 1921 taken together. Under the head of "surgery and dispensary," the expenditure was 38 per cent. above the group average, or £62 12*s.* per bed, as against £49 14*s.* per bed for the same period. Under those two heads alone there was an expenditure of £22 19*s.* per bed above the group average of comparable hospitals, and in the opinion of the committee this great difference was, to a large extent, due to lack of supervision. The secretary, although he was called superintendent, had never, in fact, been superintendent, but merely secretary to the board of management.

The report goes on to give details of the investigations made personally by the committee. In the dispensary there was great lack of control. With regard to the secretary and his staff the accommodation was quite inadequate, and the committee strongly urged that the superintendent of the hospital should be given greater powers of supervision. The committee considered it would be an advantage to the superintendent to visit some of the comparable hospitals to study the various systems of administration.

Details of the Hospital's Income.

As to income, the committee said that it was obvious that whatever help might accrue to the hospital from well-considered improvements in administration, its financial future could not be contemplated without anxiety unless the dependable income of the hospital was permanently increased. The committee quotes the following figures, the first column denoting the Brighton hospital's percentage of total ordinary income, and the second column the group average :—

	Per cent.	Per cent.
Invested funds	16	14
Workmen's contributions	3	23
Patients' contributions	17	8
Public services	10	17
By or on behalf of patients	27	25
Subscriptions	8	14
Donations	39	16

The committee considered the figures to be illuminating. It was true that the details of the income of the group from which the average was calculated differed very widely, but it would be seen that the Royal Sussex County Hospital depended for nearly 40 per cent. of its income as against an average of 16 per cent. in the other hospitals of the group on what were called donations, the term including, besides gifts usually so-called, the proceeds of bazaars, special appeals, and other non-recurring contributions.

---

[1] For the annual report of the hospital for 1922, see THE LANCET, March 3rd, p. 465.

The committee considered that the only way in which a campaign could be carried on for raising subscriptions and patients and workmen's contributions would be to act in conjunction with other medical charities, and that for this purpose there should be a central committee on which each institution would be represented, and the collection of funds regulated by district subcommittees.

The committee commended their findings to the serious consideration of the board of management. It was to be desired that the efforts now being made to establish the hospital on a firm financial basis would be successful as constant special appeals for funds were both embarrassing to the board and irritating to the public.

In a covering letter, the Rev. E. D. L. Harvey, chairman of the committee, said it was felt that the board of management failed to adopt their methods of administration to the changed conditions brought about by the war. If the coöperation of the honorary medical staff, as also the nursing staff, could be secured, the public could rest assured that steps were being taken to put the hospital on a sound financial basis.

IRELAND.

(From our own Correspondent.)

Local Government Bill in Dail Earann.

The debates on the Local Government (Temporary Provisions) Bill were continued last week in committee. All attempts to improve the Bill by amendment have so far failed. The efforts of Sir James Craig and Deputy Alfred Byrne to save for Poor-law officers some of the rights given them by the Local Government (Ireland) Act of 1919 were defeated, and a Bill introduced as a purely temporary indemnifying measure has been used to destroy statutory rights. In another section the Bill authorises local authorities to go back on the bargains made in the past two or three years with retiring officers. These officers were induced to retire, as Deputy Byrne put it, by certain promises, and the Government now steps in to annul these promises. Deputy T. Johnson, leader of the Labour Party, criticised the hospital policy of recent Poor-law reforms, in that all district hospitals were abolished and only one hospital left in each county. He stated that deaths had occurred owing to the dangers and hardships of the long journey to hospital. The Minister for Local Government, in reply, admitted that district hospitals might be necessary in some areas, and promised to consider each case on its merits. This seems to be the only concession made to any of the criticisms of the measure.

Death of a Surgeon-Probationer.

The death, from wounds received in action, of Lieut. E. W. McQuaid, a surgeon-probationer in the National Army, was reported last week. He gave his life in very gallant circumstances. A National soldier was shot down in a conflict near Newport, Co. Mayo, and Lieut. McQuaid ran to his aid. While attending him, shots were fired—whether purposely or not—and Lieut. McQuaid, although seriously wounded, continued his work and carried his patient to a place of safety. His death occurred four days later. Eugene McQuaid was a student of the Royal College of Surgeons in Ireland and of Mercer's Hospital, and had served for a time in the Royal Air Force before beginning the study of medicine. At the time of his death he was 23 years of age. He was the son of Dr. E. W. McQuaid, of Cootehill, Co. Cavan.

"*Sweepstakes Bill.*"

The Public Charitable Hospitals (Temporary Provisions) Bill, or "Sweepstakes Bill," as it is generally called, has passed its second reading by a fair majority. As stated in these columns on March 3rd, p. 455, the Bill proposes to legalise the holding of lotteries or sweepstakes in aid of charitable hospitals and convalescent homes. Such sweepstakes are to be conducted by a committee, of which the members are named in a schedule to the Bill. These members are 12 medical men connected with 12 hospitals in or near Dublin. It is noted that some of the leading charities are not represented. Section 1 of the Bill defines the institutions eligible to share in sweepstakes somewhat closely: "Public hospitals and convalescent homes in Saorstát Earann which afford medical or surgical treatment without charge or reward and which hospitals or convalescent homes *are mainly supported by the voluntary subscriptions of the charitable public.*" It is doubtful whether all the general hospitals of Dublin are not excluded by the words italicised. The main support of most of the hospitals of late years appears to come from the contributions of patients.

March 12th.

BERLIN.

(From our own Correspondent.)

Financial Difficulties of the Berlin Medical Society.

The "Langenbeck-Virchow House," the home of the Berlin Medical Society, is in danger of being given up owing to financial emergency. The society has only possessed premises of its own for seven years; meetings were formerly held in the old Langenbeck House, which belonged to the German Surgical Association—a body which only met once a year for a four days' congress, and for the remainder of the year let its accommodation to the medical society. After a time the Langenbeck House proved too small to hold the surgical congresses; in 1913 an arrangement was made between the German Surgical Association and the Berlin Medical Society to build a joint home, the Langenbeck-Virchow House, which was, in fact, opened in August, 1915, the inaugural addresses being read by Prof. Trendelenburg, formerly of Leipzig, and Prof. Landau, of Berlin. The building is lavishly furnished and contains one large hall, several small halls, a library, and the offices of both societies. At a recent meeting of the medical society the hon. treasurer stated that, although the annual subscriptions of members had been increased from 20 to 2000 marks, and notwithstanding gifts from many members, the 1923 deficit would probably be 11 million marks, even if the depreciation of the currency were to make no further progress. Messrs. Siemens and Halske, the electrical engineers, who have already hired part of the building, have, however, offered to bear all costs of heating, lighting, and salaries of the staff, and to pay off the present deficit, provided that they may have the right to lease all those parts of the building which are not required by either society. The committee were authorised to make an arrangement of that kind, provided that the contract before coming into force was agreed to by a general meeting of the society. The Surgical Association will, no doubt, also consent; otherwise the house must be given up, and the library closed. A similar arrangement already exists at the Kaiser-Friedrich House for post-graduate study, where the greater part of the building has been let to a commercial company.

A Bill for Combating Venereal Diseases.

A Bill dealing with venereal diseases will shortly be introduced in the Prussian Parliament. It proposes to enact that persons suffering from these diseases must have attendance from qualified medical men; people who either have not the means to pay a doctor themselves, or do not belong to a sick club, must be provided for by the provincial insurance boards (Landes-Versicherungs-Anstaltenhabe). These boards have already instituted advisory offices (Beratungs-Stellen) where medical advice is given gratuitously to persons with venereal disease. According to the suggested measure, persons suspected of such diseases would, when requested by a local sanitary officer, have either to produce a certificate of health or to consent to examination by a medical officer. Under certain circumstances they would be compelled to apply for admission to a hospital. Persons who know that they have a venereal disease, and nevertheless run the risk of infecting others, may be prosecuted and punished with imprisonment for a period not exceeding five years. In the case of married people, prosecution would only be instituted by request of one of the couple. Advertisement of drugs for treatment of venereal diseases would be allowed in medical and pharmaceutical journals only. Persons who permit a child suffering from hereditary syphilis to be nursed by a healthy nurse would be liable to severe punishment. The Bill would also terminate the system of registration of prostitutes, which in Germany has existed for centuries, and has lately been opposed by certain women's associations from a moral and ethical standpoint, and by medical men because it has proved useless. In Holland, Switzerland, and the Scandinavian States, it has been abolished for some time, without harm to public health. The registration, of course, concerns only the minority of these women who are openly known as prostitutes; the great majority are secret prostitutes, who come under control only when caught by the police. How small the number of public prostitutes is may be seen from the fact that in Dresden, a city of more than 600,000 inhabitants, only 250 women are registered; in Stuttgart, again, with about 300,000 inhabitants, only 25 are registered. Abolition of registration would thus have no effect on the spread of the diseases. There will certainly be considerable controversy concerning the provisions relating to the compulsory notification of certain persons suffering from disease; by this provision a medical man must give information when a patient ceases treatment before being cured, and also when the patient's occupation renders him liable to spread the disease—as, for instance, in the case of a waiter. This provision, although strictly drawn up, will nevertheless be useless; a patient might either conceal his name and profession—an easy matter in large towns—or might try to find an unscrupulous medical man; or again, will, without consulting a doctor, attempt to cure himself by using drugs formerly prescribed for his friends. It is not likely that the Bill will become law without important alteration. The proposed system of notification imposes great responsibility on the medical profession, and compels its members to give up the fundamental principle of professional secrecy. It has been alleged that this principle has been infringed already by the law concerning the notification of contagious diseases, such as scarlet fever, enteric, diphtheria, &c. There is, however, a great difference, as nobody has hitherto objected to notification of scarlet fever, whereas many people will object when the notification concerns syphilis.

A Medical Minister of State.

Dr. W. Hellpach, professor of psychology at the technical college at Karlsruhe, and a democratic member of the Baden parliament, has recently become Minister for Education of the Republic of Baden. This is the first instance of a medical man gaining cabinet rank in Germany. Some 30 years ago the late Baron von Lucius was Minister of Agriculture in Prussia, but he had never engaged in practice, and as Minister of Agriculture had nothing to do with medical matters. Prof. Hellpach, whose department includes matters connected with the universities and the health service, is well fitted for his office; he has been for many years editor of the *Aerztliche Mitteilungen*, the official organ of the Leipziger Verband.

Meat Poisoning in Freienwalde.

A few days ago about 200 people became seriously ill in Freienwalde, a small spa in the province of Brandenburg. The patients suffered from vomiting, diarrhœa, fever, and cardiac weakness, which in five patients, three of whom were children, led to a fatal issue. The investigation carried out by the local medical officer and the Berlin sanitary authorities proved that the patients had been poisoned by horse-meat, eaten as sausages. For some time the patients continued to be very weak and to suffer from cardiac debility. Horse-meat, almost unknown as a food before the war, has now become a regular dish on many middle-class tables, where the family cannot afford veal or mutton, which actually costs 5000 marks a pound—i.e., half a day's wage of a very well-paid workman. Horse-meat, as a rule, is of inferior quality, and the examination of meat, especially in smaller towns, is not always reliable.

Women Students in Prussia.

In the winter term the number of women students in Prussia was 4555, the total number of students being 46,466. Of the women students 4112 were Germans and 443 foreigners, the majority of the latter being Russians. Whilst the majority of men students belong to the middle classes, the women students are for the greater part of the upper classes. The numbers of women studying medical and allied subjects were as follows: various branches of science, 152; medicine, 777; dentistry, 159. Since 1913 women students have doubled their numbers; there has been an immense general increase since the winter term of 1917–18, although the number of women students in the faculty of medicine has considerably fallen off. In all Germany the percentage of women students is the same as in Prussia—viz., 9·7.

The Services.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. F. J. Palmer retires on ret. pay.

Maj. E. B. Booth retires on ret. pay and is granted the rank of Lt.-Col.

Maj. W. R. O'Farrell is secd. for service under the Foreign Office.

Temp. Maj. T. M. Kendall relinquishes his commn. and retains the rank of Maj.

Capt. O. W. J. Wynne retires, receiving a gratuity, and is granted the rank of Maj.

ARMY RESERVE OF OFFICERS.

Army Dental Corps.

Capt. J. B. Murray, late Spec. List, to be Capt.

TERRITORIAL ARMY.

Maj. J. Leach, having attained the age limit, is retired, and retains the rank of Maj., with permission to wear the prescribed uniform.

Capt. J. McKay resigns his commn. and retains the rank of Capt.

General Hospitals: The undermentioned relinquish their commns. and retain their rank except where otherwise stated: Maj. G. Hall, Capts. E. W. Bain, C. H. Budd, W. G. Howarth, W. B. Marshall (granted the rank of Maj.), H. J. Smith, and F. A. Hepworth (granted the rank of Maj.).

Sanitary Companies: Capt. W. Johnstone relinquishes his commn. and retains the rank of Capt.; and Lt. J. G. Saltmarsh, having attained the age limit, is retired, and retains the rank of Lt.

TERRITORIAL DECORATION.

The King has conferred the Territorial Decoration upon the undermentioned officers: Col. F. W. Higgs, and Majs. H. L. Gregory, S. R. Gibbs, and D. Shannon.

ROYAL AIR FORCE.

The undermentioned are granted permanent commissions in the ranks stated: Flight-Lt. (since promoted) A. J. Brown and Flying Officer W. E. Barnes.

E. G. S. Hall is granted a short service commn. as a Flight-Lt.

INDIAN MEDICAL SERVICE.

Col. R. C. MacWatt to be Maj.-Genl.

Lt.-Col. W. J. Niblock retires on account of ill-health.

UNIVERSITY OF SHEFFIELD.—The following appointments have been made: Dr. G. Grant Allan (Edinburgh) to the post of assistant bacteriologist; Dr. Clara D. Tingle to a demonstratorship in pathology.

Correspondence.

"Audi alteram partem."

THE OPIUM CONVENTION AND THE LEAGUE OF NATIONS.

To the Editor of THE LANCET.

SIR,—Your annotation on this subject last week referred to the importance, as regards India, of the opinion recently expressed by the joint subcommittee formed from the Health and Opium Committees of the League of Nations, to the effect that the only "legitimate" use of opium, morphine, cocaine, and the other specified dangerous drugs, is their medical use. I should, however, be glad of the opportunity to add that when this resolution of the joint subcommittee was submitted for approval to the Health Committee of the League, the British member of that Committee made the explicit reservation that in assenting to it he expressed no opinion on the interpretation of the term "legitimate" in so far as it related to the use of opium in certain Eastern countries.

The habitual use of opium without medical prescription by certain sections of the native population in these countries stands in a category apart from the problems of the abuse of morphine, cocaine, and like preparations. Many of those who are acquainted with the countries in question, and whose knowledge and views must command respect, consider that in general the traditionally guided use of opium is no more harmful, or no less beneficial, to important sections of the population than is the reasonable and temperate use of alcoholic drinks or tobacco, equally without medical prescription, in certain countries of the West. Others urge the practical objection that in the regions concerned there would not be sufficient educated medical opinion to go round, or doubt whether even the soundest medical training and knowledge qualify their possessor for the dictatorship over the habits of individuals which it is proposed to impose on him in this matter. Such contentions may or may not be justified by the facts, but at least they seemed to demand more careful consideration and analysis of evidence than the Health Committee of the League was in position to obtain when the resolution was submitted.

In the work of this Committee I usually depend on three resources to deal with questions on which, as in this case, I cannot claim any special knowledge: (1) before going to Geneva, to get primed at home by those who know the subject; (2) to be guided at Geneva by those of my international colleagues who have special experience on the matter in hand; and (3) to rely upon a special expert study of the question previously made for the League and reported to the Committee. In this instance all three failed me. The Committee had no intimation beforehand of the resolution which was proposed; three of its members, all of whom have lived and worked in the East, were absent; and no special previous investigation on this aspect of the subject had been made for the information of the Committee or of the joint subcommittee. It is rare for the Health Committee to take its responsibilities as the expert advisory body of the League too light-heartedly, but I consider that it did so in relation to this one aspect of its resolution.

I am, Sir, yours faithfully,

London, March 12th, 1923. G. S. BUCHANAN.

THE DISPENSING OF PRESCRIPTIONS.

To the Editor of THE LANCET.

SIR,—Having read Dr. G. Clark Trotter's letter in your issue of Feb. 24th on discrepancies in chemists' dispensing, as well as the many articles which have since appeared in the lay press, I feel there is a great deal to thrash out in this matter, and that it is of the greatest importance both to our own profession and to the public at large that this should be done thoroughly. There is evidently a large quantity of unstandardised B.P. preparations and drugs being manufactured and sold to-day. I remember when the Insurance Act first came into force I was flooded with advertisements from manufacturing chemists professing to be able to sell cheap drugs for insurance patients at a price at which they could never have been properly standardised; for standardisation is an expensive process. I had not worked as panel doctor long before I was called in to see an old patient whom I had frequently attended before for the same trouble, and she had always recovered in 24 hours. On this occasion I wrote out the same prescription I always gave her and sent it to the chemist. The next morning she was no better, the morning after that slightly worse, and she told me that she believed that being panel medicine it was not so good as I had always sent her previously. I was inclined to spurn this idea, but I told her I would see her mistress and suggest that I should send down a similar prescription in the name of a friend staying in the house as a guest. The patient began to improve with the first dose of the new bottle. I have had several cases similar to this.

What in my opinion is wanted is a set of regulations similar to those which control the dairy. Inspectors should be empowered to enter any wholesale or retail druggists' place and demand samples of any stock drug preparation for analysis, and if not up to B.P. standard the firm should be severely punished. A retired chemist not long ago told me that there was no law compelling a chemist to keep tinctures, extracts, infusions, &c., of the true B.P. strength, and that unless I specially signified "B.P. strength" on each prescription I wrote I could have no legal redress. The high duty on spir. vini rect. is no doubt the cause to some extent of the manufacture of worthless drugs which tempt the chemist.

What we want is first of all strict preparation of all medicines according to standards laid down in the British Pharmacopœia, and insistence under severe penalty that these regulations are carried out. Any discrepancy in a bottle of medicine could then only be the fault of the dispenser. A doctor not infrequently relies on the action of his medicine for a confirmation of his diagnosis. How many grave mistakes may be made through faulty drugs—mistakes which are difficult enough to avoid without such a handicap.

I am Sir, yours faithfully,

H. M. LEATHES, M.R.C.S., L.R.C.P.

West Drayton, Middlesex, March 11th, 1923.

THE OPERATIVE TREATMENT OF SEPTIC MENINGITIS.

To the Editor of THE LANCET.

SIR,—The interesting communication on the above subject by Mr. H. L. Martyn in your issue of March 10th calls for congratulation, comment, and criticism. The term septic meningitis is unfortunately somewhat loosely used, with the result that there is often much confusion in the clinical record of cases by different writers. My personal opinion is that no case should be regarded as one of septic meningitis unless organisms are found in the cerebro-spinal fluid. In the absence of organisms I regard such cases as cases of serous meningitis, an entirely different clinical entity.

An experience of over 25 years of hospital work and of numerous opportunities of performing operations, for no other treatment is, in my opinion, of the slightest use, for the relief of septic meningitis, leads me to say that of all the intracranial complications following septic middle-ear disease, it is the most unfavourable and, operation or no operation, is almost invariably fatal. Mr. Martyn's successful case is, therefore, a milestone on the road of surgical progress. The fact that in his case a few Gram-positive diplococci were found in the lumbar fluid and also in fluid removed from the subarachnoid space of the posterior fossa, although subsequent cultures were sterile, indicates that the cerebro-spinal fluid was infected and that the case was one of early and genuine septic meningitis, although of limited extent and slight toxicity.

In a paper read in 1913 before the Section of Otology of the Royal Society of Medicine I emphasised the importance of a detailed chemical analysis of the cerebro-spinal fluid in suspected cases of meningitis, for the reason that even before clinical symptoms point to a diagnosis of meningitis a diagnosis of its imminent advent could be made. The various metabolic processes resulting from the disintegration of bacterial life tend to destroy the carbohydrates and proteins in the cerebro-spinal fluid. Kopetsky has also shown that so long as the fluid remains alkaline, even if slightly turbid, the prognosis after drainage is good, but should it become acid and markedly turbid the prognosis is very grave. In the early stages bacteria are by no means necessarily found in the fluid, but if it still has an alkaline reaction and is capable of reducing the copper in Fehling's solution no time should be lost in effecting one or other form of drainage. At the same time I recorded four cases where extensive decompression operations over the infected area, combined with drainage of the pia-arachnoid space with multiple strands of gauze, proved successful, and since that time I have had several other successful results.

All my cases were, however, early cases, the diagnosis being made mainly on the result of chemical and bacteriological examination without waiting for the advent of classical symptoms, and further, the process was, I believe, a localised one. Never in my experience has a case of generalised septic meningitis of otitic origin recovered, although I have performed extensive decompression operations, drained the cisterna magna (Hayne's operation), the subarachnoid space, often at more than one point, and effected translabyrinthine drainage. In advanced cases the impossibility of draining the numerous sulci into which the pia-arachnoid dips must be apparent to every surgeon. Given, however, an early case, a localised process, and a mild infection, the thorough removal of the primary focus of infection, combined with the establishment of free drainage, will undoubtedly be the means of saving a few lives.

An intelligent appreciation of impending pathological processes and a careful chemical examination of the cerebro-spinal fluid are, however, essential elements for operative success. If the patient is to have a chance the very earliest indications of a commencing meningitis must be recognised. My belief is that meningitis is the most difficult complication of ear disease to diagnose, more especially in its initial phases. Experience has unfortunately made me very doubtful of success in the treatment of septic meningitis in other than quite early and localised (!) infections.

Every successful operation is a surgical triumph, provided always that a sharp line is drawn between septic and serous meningitis. No doubt every case of septic meningitis is at one phase of its existence a case of serous meningitis. Infection may or may not occur. When it does the prognosis is bad—very bad if it is diffuse; when it does not, efficient drainage is in general satisfactory and should be carried out as a routine measure, as to rely upon lumbar puncture merely is futile.—I am, Sir, yours faithfully,

Manchester, March 11th, 1923. WILLIAM MILLIGAN.

SMALL-POX AND AMAAS.

To the Editor of THE LANCET.

SIR,—Dr. de Korte, in THE LANCET of Jan. 13th, says "no one can affirm what the relationship between small-pox and amaas really is," and he appears to think that small-pox is not small-pox unless of a malignant type. It used to be common for mothers to tell their neighbours their children had not scarlet fever, but only scarlatina, and the same intent to deceive is shown by the invention of euphemisms like Kaffir-pox sour milk (amaas), or alastrim (whatever that means). Our natives do the same when they call it ihashelala, knowing full well they should say ingqakaqa.

I have been district surgeon here for 27 years, and nearly every year we have an outbreak of small-pox. The native population of about 36,000 is scattered over an area of 500 square miles. The type of disease has always been mild as regards children, and in all my time not more than a dozen have died of it. Unvaccinated children are highly susceptible, but usually show no more than 20 to 30 small pustules, and often there are fewer. If there be only one case at a kraal the vaccinated children escape; if several cases occur, the infection is more massive and vaccinated children in close contact may also have a mild attack. Men, being scarcely in contact with sick children when there are several separate huts at the kraal, have often escaped, although unprotected; but the older the patient the worse the disease, and to my knowledge an unvaccinated man died of confluent small-pox in 1906, while the small children at the same kraal had but a few spots. In that instance there was no question of two strains, as Dr. de Korte suggests; the only difference was in the age of the patient. Now that the advantages of vaccination are recognised there are, I think, but few adults left unprotected. The headmen are now alert to report when an outbreak occurs, and the neighbourhood is promptly vaccinated. The annual vaccination at various centres tends to keep the inflammable material within limits. In earlier years the disease was often unchecked for months, but even then the epidemic was local and tended to die out when the winter beer-drinking was over.

Before the days of district surgeons and vaccination there must have been similar mild epidemics year after year, but owing to the population being so scattered not sufficiently general to protect every person, and the year 1884 is a date to reckon from—the great epidemic of small-pox. The mortality was high, and the deeply pock-pitted survivors show how severe it was. 1886 was also a bad year, but the previous big epidemic was in 1849. I do not expect we shall have such a thing again in this vicinity. There is not likely to be any large accumulation of unvaccinated adults. For I believe it only requires passage through a sufficient number of adults to convert what is now a child's mild disease into the terror of pre-vaccination times.

I am, Sir, yours faithfully,
P. H. WALKER.

Mqanduli, C.P., South Africa, Feb. 17th, 1923.

A FATAL CASE OF PRE-RENAL TOXÆMIA.

To the Editor of THE LANCET.

SIR,—In Dr. W. N. Goldschmidt's interesting report of a fatal case of pre-renal toxæmia, appearing in your columns of to-day's date, a clinical sign, possibly of enlightening significance, has been missed—I refer to the distension of the abdomen. Almost from the onset of the illness this was a very marked condition, but in the endeavour to elucidate the failure of the kidneys it is not mentioned in the report. It is plain, as Dr. Goldschmidt remarks, that the illness "was not accounted for primarily by the state of the kidneys." Yet that the function of the kidneys was early impaired is indicated, not only by the œdema, but by the oliguria, the presence of albumin, red blood cells, "and numerous granular, hyaline and epithelial casts." That impairment of function, without obvious, even microscopical, change in structure in the kidneys may occur we already know. McQuarrie and Whipple, in their paper on "Renal Function in Intestinal Obstruction,"[1] have already pointed this out; but that impaired function should persist from January to June with so little change in the kidney as was found post mortem is interesting.

To what, then, is the kidney disability in this case to be attributed? Obviously not the heart. With a blood pressure of 132 mm. Hg on admission, the oliguria can scarcely be assigned to the state of the heart, which at the post-mortem several months later was found in a state of brown atrophy. The condition of the heart found at death was presumably the result of the condition of the patient during his illness, and the way he reacted to that illness—for one thing, the patient passed several months of uneasiness in bed, and towards the end (at least) vomited. Dr. Goldschmidt, in line with orthodox thought, attributes the illness (and presumably the kidney inefficiency) to a toxæmia; he titles the case one of "Pre-renal Toxæmia." But what is the evidence? Not the appearance of the kidneys five months after the play of such toxæmia, an appearance almost normal, with "all acute changes above described absent," and "chronic changes shown by thickening of capsule, only slight, as above," . . . . &c. Is it not time to push away an explanation which is only imaginary, and has only been imagined for want of a more tangible supposition—for this man took no poison. Abdominal distension was marked and troublesome, and must obviously have been persistently increased, and that such can cause impairment of kidney function is not difficult to imagine. Already we know that after severe exercise (and because of it) the urine of athletes contains albumin; and that the urine of women with child as the result of the strains of labour similarly often does so. A persistent increased pressure in the abdomen (and this patient had complained of swelling . . . . "of his 'stomach' and back for six weeks" . . . . before admission), if great enough may presumably have the same effect—not only impairing the kidneys but also the liver.

---

[1] Jour. Exper. Med., vol. xxix., 1919, p. 397.

It happens that I saw, at the request of a colleague, a similar case. A man of 54 had marked abdominal distension, the girth at the umbilicus being 37½ in., mainly due to meteorism; but there was some free fluid, œdema of feet, diminished secretion of urine, and albuminuria with casts. I thought the patient must have some malignant obstruction in his colon and that the increased intra-abdominal pressure was the essential cause of the kidney deficiency. The pressure in the rectum with the patient on his side was 30 mm. Hg (instead of 6 mm. Hg); in Sims's position it was 26 mm. Hg (instead of being negative or zero); and when on his back it was still 30 mm. Hg (instead of 10 to 14 mm. Hg). I advised draining the gut (cæcostomy), by which operation the colon could have been explored; but this course was not taken, mainly, I think, because the urine contained albumin. From reading Dr. Goldschmidt's report, I find I was probably wrong in suspecting malignant disease in my case; but in Dr. Goldschmidt's case the "sigmoid colon" was "contracted, apparently by thickening of the bowel wall . . . .; no evidence of ulceration or evident scarring" being present. To the state of the sigmoid, presumably, the abdominal distension was due. Drainage of the intestinal tract was (apparently) not considered, but the presence of albumin in the urine obviously did not prevent this, the patient having decapsulation of the kidney first on one side and later on the other performed. I think my conception is supported by the effects of these operations; it is not suprising the kidney capsule was not tense—how could the kidney swell if it be compressed sufficiently? The improvement which occurred, however, perhaps was due less to the decapsulations than to the release of two to three pints of intraperitoneal fluid in the first case and to "several pints" in the second. That complete relief was not afforded, that the illness terminated fatally, may well be explained by the persistence of the primary condition (meteorism), to which were superadded the effects of the presumable post-anæsthetic vomiting, and of the vomiting which of itself later ensued. I have already striven to urge the physiological significance of the intra-abdominal pressure, but the idea is pooh-poohed. We believe the intrathoracic pressure is negative for physiological reasons, but that the intra-abdominal pressure is positive for the same reason is not yet allowed. That pathological changes in this pressure are instrumental in causing disease I am still striving to show; that in time it will be admitted is my opinion.

I am, Sir, yours faithfully,

R. H. PARAMORE, F.R.C.S. Eng.

Brook-street, W., March 10th, 1923.

SOME LETTERS TO SIR PATRICK MANSON.

To the Editor of THE LANCET.

SIR,—Please excuse my troubling you on a small matter, but in your issue of Feb. 24th, when referring to the Tropical Diseases Library, you mentioned that "the original letters addressed to him (Sir Patrick Manson) by Sir Ronald Ross during the latter's researches on the transmission of malaria in India in 1897–98" are in the said library. I see that this matter has been repeated in several provincial newspapers and should like to say that only half the letters are in the library, the remainder being with me, and also that the School of Tropical Medicine has promised me that these documents shall not be available for readers. I am very doubtful as to the propriety of private letters being left open in public institutions during the lifetime of the writer, and, indeed, have reasons to be dubious regarding the legal aspect of the matter. I am, Sir, yours faithfully,

RONALD ROSS.

Buckingham Palace Mansions, S.W., March 9th, 1923.

⁎⁎ We share Sir Ronald Ross's doubt.—ED. L.

THE LAWS OF THERAPEUTIC IMMUNISATION.

To the Editor of THE LANCET.

SIR,—I wish to challenge certain of the "laws" contained in the St. Mary's Hospital "Codes" concerning therapeutic immunisation.[1]

Code No. 2. 1: "It cannot in any form of inoculation be theoretically essential to employ vaccines made directly from the patient." Certainly not if (*a*) you can be certain that you have got the microbe causing the disease; (*b*) that the microbe is of the same strain as the infecting microbe; (*c*) that the infection is an unmixed one. How often do those using stock antigens ascertain by bacteriological examination the infection they are dealing with or if they do, ascertain by serological tests, if specific sera are available, whether they are dealing with the proper strain? Is an antibacterial serum of any practical use in meningitis or pneumonia if it is not produced by the specific strain? It is not. Further, if stock antigens are so successful, why were they such a complete failure in the treatment of wound infections during the war, and why had Sir Almroth Wright to resort to the feeble method of salt solutions? I have never been able to get these questions answered.

Code No. 2. 3: "They [microbial antigens] may be therapeutically employed in all localised infections other than those complicated by pyrexia," and later on Sir Almroth Wright states most definitely that active immunisation is not possible in acute infections such as staphylococcal and streptococcal septicæmias, puerperal fever, for instance, and pneumonia. He writes as if microbes in the blood-stream had free access to the tissues, could pass at will through the barrier of the endothelial cells. This, of course, is not the case, it is only in those overwhelming hæmorrhagic infections where there is endotheliolysis or at the end of chronic infections where their resistance is gradually broken down that active immunisation fails. It is just in these acute infections of every kind, enteric, pneumonia, meningitis, pyelonephritis, wound septicæmias, and so on that one gets such dramatic results, just as dramatic as, if not more so than, the results obtained in diphtheria by antidiphtheritic serum. But the antigens must be specific and must be complete. I have frequently demonstrated this. I have failed when I used a sister's antigens in enteric and meningitis and succeeded dramatically when autogenous ones were used. I have failed to get results in numberless cases of every kind, and found my want of success was due to the failure to isolate an essential microbe. The reaction to these specific antigens is charmingly delicate. Sir Almroth Wright speaks as if "localised" infections were really localised. They constantly are not, and boils and the like are manifestations of chronic septicæmias; he will be surprised how often the cause of an obscure infection can be found in the urine, practically always in boils, rheumatism, and so on. Quite recently I have isolated the cause of a chronic iritis of one eye from the urine.

---

[1] Sir Almroth Wright and Others: THE LANCET, Feb. 24th, 1923.

No one ever supposed that the granules of various kinds in leucocytes were there for no purpose; one always supposed they were of the nature of proenzymes and that they were shed out at need. Of course, the animal organism has non-specific methods of defence. It is the duty of the immunisation to make these defences specific. May I repeat here again the factors that are necessary for success in therapeutic immunisation, so that Sir Almroth Wright may challenge them if he wants to.

1. The antigen must be adequate—it must be of the right strain or strains and must be virulent so that antitoxins can be produced.
2. It must be complete—that is, contain all the kinds of microbes causing the infections.
3. The doses must be given at suitable intervals—that is, not during the negative phase.
4. A dose must be attained such that sufficient specific antibodies are produced to combat the infection present.
5. The patient must be capable of response to the stimulus.

In an address before the Royal Society some years ago Sir Almroth Wright stated that microbial antigens were of little use in chronic infections. This also is not the case. If the foregoing rules are followed just as great success is obtainable in chronic infections of every kind, but a much higher degree of immunity must be reached.

No one will be convinced of the truth of my assertions until he has either tried my methods or until I have demonstrated them. I shall be very glad to demonstrate them at St. Mary's Hospital or any other convenient place, and am quite prepared to stand or fall by the results. I apologise for the length of this letter, but the subject is of the first importance.

I am, Sir, yours faithfully,
W. M. CROFTON.

Laboratory of Special Pathology, University College, Dublin, Feb. 26th, 1923.

DOCTORS AND BLIND MASSEURS.

To the Editor of THE LANCET.

SIR,—I am much interested in the work of the Association of Certificated Blind Masseurs, of which I have the pleasure to be President. It has recently published leaflets giving the addresses of its members in London and all parts of the British Isles. May I venture to suggest that all registered medical practitioners should obtain copies from the Secretary of the Association, 224–6–8, Great Portland-street, London, W. 1? These leaflets show that members of the Association, both masseurs and masseuses, are established in practically all the large towns, as well as in all parts of London and the suburbs. As massage is work which, it is generally recognised, can be most efficiently carried out by blind people properly trained, those doctors who can see their way to the employment of members of this Association will be aiding in a work of national importance.

I am, Sir, yours faithfully,
Liverpool, March 8th, 1923. ROBERT JONES.

GANGRENE OF THE TOES FOLLOWING CONSUMPTION OF ERGOTISED RYE BREAD.

To the Editor of THE LANCET.

SIR,—Dr. Parkes Weber's letter in your issue of March 3rd affords us the opportunity of stating that our investigations of the case of gangrene associated with the eating of rye bread are not yet completed. We are bearing in mind the cases of gangrene—thrombo-angiitis obliterans—reported amongst Jews by Dr. Parkes Weber and others. The ætiology of thrombo-angiitis obliterans is admittedly obscure and excessive cigarette-smoking seems an insufficient ætiological factor, whereas, in the case recorded by us of gangrene of corresponding toes in succeeding autumns, it has been proved that the rye bread, which he was in the habit of eating, contained active ergot and was capable of producing cyanosis of the cock's comb. To the naked eye the rye bread did not show evidence of contamination, and it would be of interest to know on what grounds Dr. Parkes Weber excluded the possibility of ergotism as an ætiological factor in his cases.—We are, Sir, yours faithfully,

R. E. KELLY.
Liverpool, March 7th, 1923. W. J. DILLING.

HOSPITAL SAVINGS ASSOCIATION.

To the Editor of THE LANCET.

SIR,—A brief reply to the letter of Lord Hambleden on the above subject seems necessary. His answers to the five points given in the letter from Mr. F. W. Davy and Dr. H. Campbell, published in your issue of Feb. 3rd, leave much to be discussed.

1. It was stated that the scheme creates a self-interested body which would seriously interfere with the present independent management of hospitals. Lord Hambleden says it will do nothing of the kind. If the scheme be generally adopted, however, a body, which may be constituted of hospital patients up to two-thirds of its total strength, will eventually have under its control the disposal of the funds which its members have contributed. Pressure brought on boards of management by such bodies, whatever its effect, must of necessity create a new element, not to be confused with the admirable practice of endeavouring to directly associate wage earners with management by the presence of working men as members of committees.

2. Lord Hambleden states that "It is not an insurance scheme." It is not, but it imports, despite all statements to the contrary, an element of insurance risk—a risk shared alike by both hospital and contributor—importing also every defect of insurance with none of its advantages.

3. With regard to almoner inquiries, Lord Hambleden's reply would convey the impression that the scheme merely relieves hospitals of this troublesome routine duty, by arranging for it to be done by the local branches of the association. On examination of the organisation of existing branches I find that the person charged with this responsible duty is to be chosen by the patients themselves in the following manner. "Call a meeting in the workshop . . . put a resolution and get the scheme adopted. Agree on a secretary who will be supplied with vouchers available for yourselves and families." Hospitals are thus asked to substitute this delegate for their own trained officials.

4. Lord Hambleden evades the importance of dealing with the question of payment of medical staffs which the adoption of the scheme necessitates, by stating that this is merely "a question of hospital management." It certainly is, but is one of a gravity which would not have to be faced did not the scheme force it forward. Adopt the scheme and there can be but one consequence—viz., a claim for payment for services from some members of the hitherto honorary medical staffs, which would logically involve payment to all, and this undoubtedly would be distasteful to a majority of those holding honorary hospital appointments in London.

5. How hospitals, which are to be controlled by workshop committees, in which the inquiry work is to be done by patients and in which the medical staffs are paid, are to recognise themselves as being still within the "voluntary system" should be explained by the Hospital Savings Association.

I am, Sir, yours faithfully,
March 9th. A SECRETARY OF A LONDON HOSPITAL.

WOMEN IN THE POST OFFICE MEDICAL DEPARTMENT.

To the Editor of The Lancet.

Sir,—May I ask you to be good enough to allow me to reply briefly to the singularly misleading remarks which appear in the letter signed "Clericus" in your issue of March 10th.

He accepts as an axiom the statement that "women cheapen labour." This, however, is only true when women are offered and accept lower pay than men for the same work. It is obviously untrue where an equal standard of payment is maintained. The contention of the Medical Women's Federation is that the traditional loyalties of the medical profession demand that its members stand by each other in refusing to accept a standard of remuneration in public service which is deemed inadequate by the profession as a whole. If medical women in any number should depart from this standard of conduct one of two results would follow: either the work of the public services would fall more largely into the hands of women through demands for economy, or their men colleagues would eventually be driven to accept a similar low rate of pay.

That the resistance of organisations of medical women to inequality of treatment checks any tendency to lower standards was shown when the Board of Education advertised for men and women to fill the posts of school medical officers, offering a lower salary to women. Through the efforts of the London Association of Registered Medical Women, qualified women refused posts on those terms, and with the loyal coöperation of many men in the profession the resistance was successful. The higher standard was secured and has been maintained since for men and women alike.

Again "Clericus" suggests that women with higher qualifications and hospital experience are not available for work in the Post Office service, but he does not explain why this is the case. It is significant that when an unequal standard was introduced in a post advertised in 1911, several women with university degrees and hospital experience withdrew their applications, and we maintain that public services suffer when conditions are such that the more highly qualified candidates are not forthcoming. Since the same post became vacant in 1914 no advertisements for medical women have appeared; the post has been filled by invitation or chance application, and not by open competition. Women with higher qualifications have therefore had no opportunity to apply had they been willing to do so.

The Medical Women's Federation do not dispute the justice of demanding a higher standard of qualification and experience for the more highly paid posts. They do, however, believe that it is inimical to the welfare of the medical profession and of the general public to base the standard of pay on the sex of the individual instead of on his or her qualifications and experience. It is scarcely necessary to reply to the assumption that "no woman could possibly perform the duty of attending to accidents of all kinds and degrees with other complicated work" since they have done such work for years in many hospitals and are doing it in increasing numbers every year.—I am, Sir, yours faithfully,

Florence E. Barrett.
President of the Medical Women's Federation.

9, Clifford-street, London, W. 1, March 13th, 1923.

To the Editor of The Lancet.

Sir,—I should be glad if you would allow me a short space to comment on the letter of "Clericus" in your issue of March 10th, lest his statements if uncontradicted should be accepted as truths. It is, however, difficult to meet such a blend of "inside information," distortion, and inaccuracy. I am unable to say what changes were made in 1883 in the salaries of men medical officers, but a medical woman was then appointed and her salary was, I believe, the third highest in the medical department, and after 40 years this relative position still obtains—so, according to the arguments of "Clericus" himself, this business Post Office presumably considers that the work of medical women is not without value.

From 1883 to 1895 only one medical woman was employed. In 1895 two new posts for assistant medical officers were created, for a man and a woman respectively, each with the same salary—viz., £200–£300. No change was made till 1911, when again a fresh post was created on each side, but the scales were then altered so that the man was offered £180–£400 and the woman £180–£300. Several of the women candidates withdrew their applications when they heard of this difference. Between 1883 and 1914 five medical women in all had entered the service but three had retired, one on pension on reaching the age-limit and two resigned voluntarily to take up more congenial work. The letter of the Medical Women's Federation referred only to retirement on pension, not to voluntary resignation. Since the last resignation in 1914, the war intervening, there were no fresh permanent appointments made until last year, the work being carried on for nearly eight years by the two remaining permanent officers and a succession of locum tenentes. It is therefore not correct to say that only one resignation has occurred in 41 years and the deduction therefrom is not valid; but this statement was probably due to a misunderstanding.

With one exception all the women medical officers have had university degrees; all of them had held such resident posts in hospitals—two of them, at least, in large general hospitals—and in infirmaries or other institutions, as were open to women; the average age on appointment was 28. A reference to the last advertisement for a male medical officer will show that no such conditions as those mentioned by "Clericus" were imposed, but as there were a very large number of applicants the authorities naturally and rightly selected those with the best qualifications and experience and gave the preference to men who had served in the war. The last appointments for women were made under exceptional circumstances, but even so "Clericus" is inaccurate both as regards age and experience and he treats one exception as a normal condition.

I do not think that anyone, who really knows, would say that the women medical officers do less work than the men, and for the most part their duties are strictly comparable in nature. The men certainly have under their supervision a very much larger proportion of staff engaged in more or less heavy manual labour and therefore naturally more liable to accidents, but even women sometimes fall downstairs or through a skylight or have pulmonary or other hæmorrhages, and whatever wounds, fractures or other mischances occur amongst the 14,000 women under the charge of the women medical officers are dealt with by them. Claims for injuries against the Post Office, workmen's compensation cases, and cases of industrial fatigue are also dealt with by the women medical officers. They are not usually required to visit provincial offices, but when a special report on the work of telephonists was called for some years ago the senior woman medical officer was included in the Commission of Inquiry which visited large exchanges in various parts of the country from Glasgow to Cardiff.

The present Principal Woman Medical Officer was originally appointed as Assistant Medical Officer in 1895 at £200–£300, like all her men and women colleagues who were appointed as Assistant Medical Officers between 1895 and the earlier part of 1911. An appointment in 1889 under different conditions has nothing to do with the argument.

I am, Sir, yours faithfully,

March 13th, 1923. Medica.

Mr. Neville Chamberlain, Minister of Health, has appointed Mr. Douglas Veale of the Ministry of Health to be his private secretary.

Obituary.

NORMAN DALTON, M.D., F.R.C.P. LOND., M.R.C.S. ENG.,

CONSULTING PHYSICIAN TO KING'S COLLEGE HOSPITAL.

Dr. Norman Dalton, who until last year was senior physician to King's College Hospital, died on March 9th, at the age of 65. He was the last surviving son of the late Dr. E. T. E. Dalton, postmaster of British Guiana, and was educated in the colony and afterwards at Christ's College, Finchley. Later he entered King's College, London, and qualified M.R.C.S. Eng. and L.S.A. in 1879. In 1880 he graduated M.B. Lond,, with honours in medicine and obstetric medicine, and two years later proceeded to the M.D. degree. He became a Member of the Royal College of Physicians of London in 1886, and in the same year was appointed assistant physician to King's College Hospital, becoming full physician in 1900. He obtained the Fellowship of the Royal College of Physicians in 1894. Norman Dalton was a Fellow of King's College, where he was at one time professor of pathology and anatomy, and later joint lecturer in medicine at the medical school. He also held the post of examiner in medicine in the University of London and to the Conjoint Board; he was physician to the National Provident Institution for Mutual Life Assurance and medical officer to the London branch of the Scottish Union and National Insurance Company. He was consulting physician to the Thames Ditton Cottage Hospital, physician to the Public Dispensary, Drury-lane, London, and honorary surgeon to the North-East London Hospital for Children. He was at one time lieutenant-colonel in the Territorial army.

A colleague writes: "The death of Norman Dalton will be deeply regretted by a wide circle of friends to whom his simple and unaffected nature had endeared him. Many generations of old King's students to whom he had been not only a popular teacher but a close friend and a valued adviser will also mourn his loss. As a medical student small in stature and none too robust in health, he was attracted to the more intellectual rather than to the athletic side of hospital life. From an early period he began to make his mark as a close, painstaking observer endowed not only with the power of learning but with the ability to impart knowledge to others. When appointed to the staff of his hospital he became a most popular teacher of medicine. There was about him a spirit of personal friendly interest in all who came into contact with him that made even the most junior students feel that he was their friend as well as their teacher, that their interests were his, and that he had a personal gratification in their success. The affectionate sobriquet of "little Dolly" by which he was known to generations of King's men bears witness to the personal esteem in which he was held. In him we lose one of the older school of physicians, for he was a man whose chief interest lay in the purely clinical side of his work. His early medical education was acquired before bacteriology or clinical pathology had made their influence felt, and though he, like everyone else, had to acknowledge their importance, his innate conservatism always kept him true to his early ideals, observation at the bedside and in the post-mortem room. As a clinical observer he was shrewd, sound, and painstaking to the last degree. His opinion was sought and valued by all who saw his work; his teaching, if slightly dogmatic, was lucid, precise, and most helpful to the younger men.

"Dalton was perhaps most in his element in the post-mortem room. For many years he was professor of morbid anatomy, and his tenure of office lasted right up to the removal of the hospital to Denmark Hill, when the work increased beyond his power to cope with it. He never wrote much; he was in every way averse from the jostling and pushing of modern life. Anything that savoured of advertisement or self-seeking was abhorrent to him. He was content to do his work as well as he could, and he did it with as little fuss as possible. He was apt to be distrustful of new theories and new movements, and the decision to uproot the old hospital that he had served for so many years from its dingy and inadequate quarters in Portugal-street to its new site at Denmark Hill caused him much anxiety; however, he was one of the first to acknowledge and rejoice in the success that followed the experiment. The war tried him severely, but he was able to complete his term of office on the active staff of the hospital, retiring at the age of 65 last summer. None among those who have been educated within its walls could have been more jealous of the honour or more zealous for the advancement of King's College Hospital. We mourn the loss of a loyal friend, a sound teacher, and a most upright and single-minded colleague."

LAURENCE BRUCE ROBERTSON, B.A., M.B. TORONTO, F.A.C.S.

Major Bruce Robertson, whose death is reported from Toronto, was assistant surgeon to the Hospital for Sick Children at Toronto and assistant in clinical surgery and demonstrator of anatomy in the Faculty of Medicine. Never a strong man, he nevertheless attained a high reputation as a skilled and kindly surgeon. He was best known to Englishmen as the surgical specialist to No. 2 Canadian Casualty Clearing Station, which was situated at Rémy Siding, near Poperinghe, during the campaign of 1917. Over 30,000 casualties passed through his station during this period and 6000 major operations were performed. He took a great interest in blood transfusion on which he wrote a number of pamphlets. He was among the first, if not actually the first, to use this method in the British Army, and he did much to familiarise British surgeons with this valuable method of bringing back to life men who were on the verge of death. He broke down under the strain, and it seems probable that his death at the early age of 37 years was due to his exertions on behalf of the wounded.

JOHN YOUNG, M.D. GLASG., L.R.C.S. EDIN.

WITH the death of Dr. J. Young, at the age of 86, there passed away almost the last of the older generation of medical men who were lecturers at the early Sheffield School of Medicine in Surrey-street. Dr. Young qualified L.R.C.S. Edin. in 1863 from the University of Glasgow, taking his M.D. Glasgow in 1865. He settled in practice at Sheffield and for some years in the "eighties" he lectured on materia medica during the summer session at 8 A.M. to students of the medical school, alternating with the lecturer on botany, the late Edward Birks. This work, like that of all the teaching staff in those days, was honorary, but whereas most of the other lecturers held hospital appointments and as such found it desirable to keep in touch with students, in Young's case there was no such stimulus. He was in general practice throughout and never held any hospital appointment in Sheffield. His enthusiasm may probably be attributed to an extreme energy and an instinctive love of teaching. His interest in the medical school never ceased. For years he was an active and constant attendant at its council meetings and a keen supporter of its development. Until quite recent years he was to be seen at the annual meetings of the Court of the University.

Dr. Young was an honourable, hard-working, conscientious practitioner of the best type, and many young Sheffield doctors have owed him a debt of gratitude.

PRESENTATION TO A MEDICAL MAN.—On March 8th, at the North British Station Hotel, Edinburgh, Dr. A. A. Matheson was presented with an illuminated address and silver tea service, and Mrs. Matheson received a fitted dressing case. The presentation was made on behalf of the Jewish community to which Dr. Matheson has been medical adviser for many years.

Medical News.

Royal College of Surgeons of England.—At an ordinary Council meeting, held on March 8th, Sir Anthony Bowlby being in the chair, a report from the Board of Examiners in Dental Surgery was read, respecting candidates found qualified for the Licence in Dental Surgery and Licences were granted to 73 candidates, whose names are given below. —Mr. H. S. Clogg was elected a member of the Court of Examiners to fill the vacancy caused by the resignation of Mr. James Sherren.—The Council accepted with appreciation the gift by Sir John Bland-Sutton to the College of a copy by Mr. Dorofield Hardy of the portrait of John Hunter by Robert Home.—Mr. V. Warren Low was appointed a representative of the College on the Senate of the University of London for the period from May 8th next to the second Tuesday in May, 1927, in the vacancy occasioned by the retirement of Mr. F. F. Burghard.—Dr. W. S. A. Griffith was re-elected the representative of the College on the Central Midwives Board for the period of one year from March 31st, 1923.

Licences to practise dentistry were conferred upon the following candidates, who have passed the requisite examinations and have complied with the by-laws :—

A. M. Abercrombie, Birmingham ; P. K. Albertyn, Guy's ; F. W. Barton, Royal Dental ; Mabel H. B. Blakesley, Univ. Coll. ; E. A. J. Bradley, Guy's ; A. E. Butler, Manchester ; B. J. Cilliers and H. A. Clarke, Guy's ; H. Cole, F. W. H. Cowper, H. I. Dingle, P. Domb, and H. F. Dunkin, Royal Dental ; B. G. E. Evetts, London ; C. D. Farris, Guy's ; G. F. Ferris and J. Fletcher, Royal Dental ; W. R. Gray, Univ. Coll. ; D. W. Griffith, Guy's ; Helene M. Gubb, Royal Dental ; R. Hofmeyr, Guy's ; M. L. Hooker, Univ. Coll. ; S. G. House, Bristol ; W. F. Howe, Guy's ; Ida Jacob and S. A. Jollye, Royal Dental ; J. E. Jones, Guy's ; T. W. Jones, Royal Dental ; F. A. Kerrison, Guy's ; G. R. Kull, Royal Dental ; M. S. Lewin, London ; S. E. Lewis, E. A. Lloyd, and J. B. Maree, Guy's ; L. R. Marsh and H. K. Mason, Univ. Coll. ; R. Maxwell, R. C. May, H. S. Murray, and S. R. Mutch, Guy's ; J. Newman, Manchester ; A. M. Nodine, Royal Dental ; D. W. C. Northfield, L. B. Osborne, and J. R. Palfrey, Guy's ; A. R. Parkin, Sheffield ; F. R. Payne, Guy's ; B. Peacock, Durham ; H. L. Poland, Royal Dental ; C. T. Pomeroy and A. W. Reynolds, Guy's ; J. Robinson, Royal Dental ; F. A. Sampson, Guy's ; E. Samson, Middlesex ; W. O. Sims and E. G. Smallbone, Guy's ; Kathleen C. Smyth, Royal Free ; J. L. Soutter, Univ. Coll. ; P. A. Tucker and C. P. Urbani, Guy's ; J. G. H. Vidler, Royal Dental ; O. R. Vignale, Univ. Coll. ; F. A. Walker, Guy's ; V. D. Walker, London ; R. P. Wall, Royal Dental ; E. S. Walmsley, Guy's ; R. O. Warner, Sheffield ; A. R. Webber, London ; W. A. Windsor, Univ. Coll. ; B. T. Wyatt, Royal Dental ; W. E. Zobel, Univ. Coll. ; and G. Zondagh and I. M. Zondagh, Guy's.

Harveian Society.—A meeting will be held at Paddington Town Hall on March 22nd, at 8.30 P.M., when a discussion on the Treatment of Duodenal Ulcer, Operative and Post-operative, will be opened by Sir Berkeley Moynihan, to be followed by Dr. Arthur Hurst, Mr. James Sherren, Dr. Robert Hutchison, and Dr. Moreland McCrea.

Hunterian Society.—The Hunterian Oration on the Evolution of the Modern Views on Septic Peritonitis and its Applications will be delivered by Mr. H. W. Carson on March 19th, at 8.30 P.M., at the Mansion House. A discussion will follow. Among those intending to take part are Mr. T. H. Openshaw, Dr. L. S. Dudgeon, Mr. Percy Sargent, Mr. J. D. Malcolm, Mr. Girling Ball, and Mr. C. H. Fagge.

Royal Medical Benevolent Fund.—At the last meeting of the committee, held at 11, Chandos-street, Cavendish-square, London, W. 1, 34 cases were considered, and £506 10*s.* was voted to 32 applicants. The following is a summary of some of the cases relieved :—

Widow, aged 70, of L.M. Dub. and L.A.H. Dub., 1878, who practised in Ireland and died in 1895. Applicant has two married daughters, but they are unable to render her any assistance. For some time past she has been able to pay her way, but a granddaughter, her sole support, is now out of work and they owe rent. Applicant's only income Old Age Pension. Voted £26, £8 paid to meet rent and the balance in monthly instalments.

L.R.C.P. Lond. 1889, L.S.A., 1888, aged 60, married, two children. Applicant unable to attend to his practice owing to indisposition caused by a fracture of neck of right thigh bone through falling unconscious on deck during a voyage for his health. This joint was affected with chronic rheumatic arthritis contracted in 1915 when in cavalry on East Coast. Voted £25.

Daughter, aged 58, of L.S.A., 1870, M.R.C.S., 1873, who practised in Sheffield and Kent and died in 1920. Through the embezzlement of the bulk of the late father's estate by solicitor, the applicant and her two sisters find themselves in very reduced circumstances, and they have only £67 per annum to live on at present while the small amount of capital lasts. Voted £12 in 12 instalments.

Daughter, aged 18, of M.D. Dub., 1898, L.S.A., 1895, who practised in Birmingham and died in 1922. Applicant left school in July, 1922, and took a post as children's nurse at £36 per annum. She asks the Fund to give her a grant towards training and maintenance to be able to secure a good appointment and become quite self-supporting. Applicant's mother is delicate and has only £120 a year derived from sale of practice and is unable to help to any extent. Voted £25 and referred to Guild.

Wife, aged 52, of L.R.C.P. & S.I., 1894. Applicant's husband was in the Army of Occupation, he had a stroke in March, 1922, and was demobilised in August, 1922, and is trying for a pension. He is still in hospital and has to pay 4*s.* 6*d.* per day. The daughter is seeking a post as secretary and the mother is doing all she can to keep the home together. The small amount of capital is rapidly diminishing to meet expenses. Voted £20.

Wife, aged 48, of M.R.C.S. Eng. and L.S.A., 1886, who practised in Leeds. Applicant's husband had a stroke in May, 1922, and they are obliged to leave the house to make room for successor. They have been living on their savings up to now. Applicant has had the offer of a house to be able to take resident patients and asks the Fund for money to pay the quarter's rent required in advance. Voted £20.

Widow, aged 57, of L.R.C.P. & S.I., 1879, who practised in Kent and died in 1901. Owing to the death of mother and a cousin, whose annuities ceased at their death, applicant is now without any means and is dependent on friends. Voted £18 in four instalments.

L.R.C.S.I., 1871, aged 74, who practised in Yorkshire. Wife is suffering from cancer and not expected to live more than a few weeks. Applicant injured at sea in Mercantile Marine, 1917, and now suffering from want of nourishment. Voted £26 in 12 instalments.

Subscriptions may be sent to the hon. treasurer, Sir Charters Symonds, K.B.E., F.R.C.S., M.S., M.D., at 11, Chandos-street, Cavendish-square, London, W. 1.

International Society of Medical Hydrology. The first annual meeting was held at the house of the Royal Society of Medicine on March 8th, Dr. Fortescue Fox, President for the year, in the chair. Members were present from Bath, Buxton, and Harrogate, as well as from France, Switzerland, and Czecho-Slovakia. A representative for Hungary was elected, making a total of 18 countries represented ; 15 new members were also elected. A new rule was passed, widening the basis of membership in the society. A letter from Prof. Barduzzi, of Sienna, was presented, advocating a more systematic teaching of hydrology. It was agreed to publish the *Archives of Medical Hydrology*, which are circulated in 58 countries, three times in the current year. Dr. Ladislas Schmidt, of Pistany, Czecho-Slovakia, read a paper by himself and Dr. Ed. Weisz on the use of hyperthermal radio-active mud as a method of home treatment.

National Association for the Prevention of Tuberculosis.—The ninth annual conference will be held at Birmingham on July 12th and 13th, and will be presided over by Sir Arthur Stanley, Chairman of Council of the Association. On the 12th the morning session will be devoted to a discussion on the Care of Advanced Cases of Tuberculosis, especially as Regards Prevention of Infection ; in the afternoon the Extent and Nature of Damage Done by Tuberculosis Derived from Infected Milk and Methods of Prevention will be dealt with. On the 13th in the morning the Relative Prevalence of Tuberculosis Among Workers in Different Trades, and Methods which are Likely to Reduce the Incidence in Special Trades will engage the attention of delegates, and in the afternoon Proposed Amendments of Procedure in the Notification of Tuberculosis. Among the medical men who have already promised to take part are Sir Gilbert Barling, Prof. E. L. Collis, Dr. G. Lissant Cox, Prof. S. Lyle Cummins, Dr. W. H. Davison, Dr. R. Dudfield, Dr. John Fraser, Sir Henry Gauvain, Dr. Fergus Hewat, Dr. H. W. McConnel, Dr. A. S. M. Macgregor, Dr. F. N. Kay Menzies, Dr. Marcus Paterson, Sir Robert Philip, Dr. Nathan Raw, Prof. John Robertson, Dr. William Robertson, and Dr. Cecil Wall. An address on the Actual Position of the Tuberculosis Problem To-day will be delivered on the evening of July 13th. A special meeting will be held to discuss the important subject of the Work of Tuberculosis Care Committees. The conference is open to all bodies concerned in any way with the subject of tuberculosis and to all other interested persons. Further information may be obtained from the secretary of the Association at 20, Hanover-square, London, W. 1.

Yarmouth Hospital and Convalescent Home. At the annual meeting held on March 1st the board of management reported that the townspeople continued to support the hospital loyally, with the result that the income was well maintained. The report only covered the last seven months, during which period 392 patients were admitted, in addition to 43 remaining under treatment on May 31st, making a total of 435. The daily number of beds occupied was 48, compared with 45·4 for the preceding 12 months. The number of operations was 167. New medical and surgical out-patients numbered 349, and there were 1026 new cases treated in the casualty department.

In the dental department 116 cases were treated; there were 121 new ophthalmic cases, and 97 new patients in the X ray department. The total income of the hospital from ordinary sources was £5054 3*s*. Substantial support was given to the institution by most of the employees of the business houses and factories, and by the majority of the residents in villages served by the hospital. The annual meeting of subscribers to the Yarmouth Convalescent Home was held on Feb. 28th. The secretary stated that unfavourable weather caused a smaller number of admissions last year than in 1921, but London sent 224 children, Norwich 62, and other places 21—a total of 307. The financial statement showed a total expenditure of £1059. On the income side, subscriptions amounted to £478; donations, £56; Hospital Saturday Fund, £155; church collections, £10 15*s*. 6*d*.; dividends, &c., £137; patients' payments, £202, showing a deficit of £19 1*s*. 2*d*. Yarmouth's high position among health resorts for average sunshine was a great asset to the home. This was shown by the rapid progress of the children's convalescence, and by the large number of cases of complete recovery.

CHELSEA CLINICAL SOCIETY.—The annual debate of this Society will be held in the Club Room of St. George's Hospital Medical School, London, S.W., on March 20th, at 8.15 P.M., when a discussion on Visceroptosis will be opened by Sir Charlton Briscoe, who will be followed by Dr. Robert Hutchison, Mr. Ivor Back, and Mr. Mortimer Woolf.

THE Council of the Royal Institution of Mining and Metallurgy have awarded to Dr. Leonard Hill a gold medal, instituted by the Consolidated Gold Fields of South Africa, Ltd., in recognition of his valuable researches on ventilation, and in particular of his paper, Ventilation and Human Efficiency, contributed to the Transactions of the Institution.

THE IRISH LOCAL GOVERNMENT (TEMPORARY PROVISIONS) BILL.—There is some reason to believe, our Irish correspondent writes, that certain of the clauses of the Local Government (Temporary Provisions) Bill, at present before the Parliament of the Free State, are ultra vires in that they appear to run counter to the terms of the treaty, which is embodied in the Constitution of the Free State. Mr. T. Hennessy, honorary secretary of the Irish Medical Committee, makes a good case for this view in a letter to the press published last week. He points out that the Bill deprives certain public officers of rights conferred on them by the Local Government (Ireland) Bill of 1919. But the treaty provides that public officers shall not be treated worse than under the Government of Ireland Act of 1920, and that Act in its turn secures to public officers all rights and privileges conferred on them by successive Local Government Acts, including that of 1919. It is probable that this view of the case, which was not put before the Dail during its debates, will receive due attention in the Senate.

DONATIONS AND BEQUESTS.—The Chelsea Hospital for Women has received a grant of £500 from the trustees of the Zunz bequest, and £40 from the "Prosperity" Trust.—The late Mrs. James Wood, of Willaston, Nantwich, who left £18,000, the income of which is to be paid to her aged sister for life. On this lady's death £500 is to be paid by the trustees to the Nantwich Cottage Hospital, and £1000 to the Crewe Cottage Hospital. The residue of the estate, about £15,000, is to be devoted to such charitable objects as the trustees shall decide at Nantwich, Crewe, and Willaston.—By the will of the late Dr. T. H. Kellock, surgeon to the Middlesex Hospital, the testator left £500 to the Hospital for Sick Children, Great Ormond-street, to be expended, if possible, in some specific object which shall not increase the annual expenditure of the hospital; £100 to that hospital as a permanent endowment of the Medal for the Nurses' Prize instituted by him; £100 each to the Santa Claus Convalescent Home for Children, Highgate, N., the Invalid Children's Aid Association, and the National Society for the Prevention of Cruelty to Children; and £50 each to Miss Sharman's Orphan's Homes, Southwark, S.E., and the St. Giles Christian Mission.—The late Mr. John Edgar, of Kingsmead-road, North Birkenhead, left by will £250 to the Birkenhead Borough Hospital; £100 each to the Children's Convalescent Home, West Kirby, the Liverpool Convalescent Institution, Woolton, and the Birkenhead and Wirral Children's Hospital, Woodchurch-road, Birkenhead.—The late Councillor David Morgan, of Glandyfi, Tredegar, Mon., has left the bulk of his property, valued at over £11,000, to the Tredegar Cottage Hospital, subject to the life interest of his wife.—Mrs. Jessie Marion Meade-King, of West Derby, Liverpool, left £32,450. On the death of her brother £5000 goes to the Royal Liverpool County Hospital for Children and £3000 to the Liverpool Queen Victoria District Nursing Association.

Parliamentary Intelligence.

NOTES ON CURRENT TOPICS.

Pharmacy Bill.

ON Thursday, March 8th, Mr. O'Grady introduced a Bill into the House of Commons "to regularise the position of all persons trading as chemists and druggists or pharmacy store proprietors in the sale of drugs, the dispensing of doctors' prescriptions, and the sale of patent medicines." The Bill, which was read a first time, proposes that after Jan. 1st, 1925, the Incorporated Society of the Institute of Chemistry shall alone possess the power to authorise any person to assume or use the title "chemist" and the Incorporated Society of the Institute of Chemistry shall conduct examinations for such purpose. Such examination and registration fees shall be payable as are fixed by the Council of the Institute of Chemistry. Clauses 3 and 4 define the powers of the Pharmacy Society to place persons on the pharmaceutical register and to conduct examinations. A central council is to be appointed under the Bill, consisting of 16 members, of whom 4 are to be appointed by the British Medical Association, 4 by the Incorporated Society of the Institute of Chemistry, 4 by the Pharmaceutical Society, and 4 by the Incorporated Society of Pharmacy and Drug Store Proprietors of Great Britain, Ltd., together with a chairman appointed by and a member of the Privy Council.

Clause 8 provides: With regard to the sale of poisons in addition to any conditions now contained in any Act of Parliament the following provisions shall have effect:—

(*a*) So far as regards such poisons and poisonous preparations or compounds thereof as may be sold only on the production of a medical practitioner's prescription or order, a copy of such prescription or order must be duly entered by the registered pharmacist in a special book for the purpose, and the prescription must be duly signed with the name and address and academic qualifications of such medical practitioner and no such prescription or order shall be repeated without a further prescription or order being provided;

(*b*) As regards such poisons as may be supplied by a registered pharmacist without such prescription or order of a medical practitioner, the registered pharmacist shall only sell such poison with a printed label which shall have printed upon it the maximum pharmacopœia dose and the description of the antidote, if any, to such poison, together with the name and address of the seller of such poison;

(*c*) As regards such poisonous articles as are sold for domestic or commercial purposes, not being for human consumption, such poisonous articles shall be supplied only in distinctive bottles or containers with the words "poisonous, not to be taken" legibly inscribed upon a label thereon, together with the name and address of the seller.

Clause 9 deals with the powers of wholesale chemists to sell poisons, and provides that no person shall carry on business as a wholesale or manufacturing chemist who is not or does not employ at least one person on the pharmaceutical register. Under Clause 10 a system of licences is proposed for the sale of non-poisonous articles. Such licences are to be only for one year. The pharmaceutical register is to be under the control of the Central Council. Clause 12 provides that no advertisement in connexion with the sale of any medicinal article shall refer to the curative powers of such article with reference to more than three specific complaints which must be of a similar pathological character and no such advertisement shall be issued without the previous sanction of the Central Council. Any person infringing the provisions of the Act is to be liable on summary conviction to a fine not exceeding £5 for every such offence. The Act does not apply to Ireland.

HOUSE OF COMMONS.

WEDNESDAY, MARCH 7TH.

Economy in National Insurance.

Dr. WATTS asked the representative of the Ministry of Health the total number of insurance committees in England, the total number of members, and the total expense of the meetings, including railway fares, payments to members for loss of time and for subsistence; and whether, in the interests of economy, he was prepared to consider the advisability of reducing either the number of committees or the number of members of each committee.—Sir W. JOYNSON-HICKS replied: There are 128 insurance committees in England, with an aggregate membership of 3130. In 1922 the total expenditure on travelling was £2065, and the payment for subsistence and loss of remunerative time was £1658. The National Health Insurance Act, 1921, reduced the minimum membership from 40 to 20, and the maximum from 80 to 40, and the revised limits have not yet been in operation sufficiently long to indicate whether any further reduction in the size of these committees is practicable.

Insanitary Slums in Poplar.

Mr. Lansbury asked the representative of the Ministry of Health if he was aware that a considerable amount of slum property in the borough of Poplar had been abandoned; that the local authority had no means of tracing the owners, consequently many people were living under insanitary conditions owing to the local authority being powerless to deal with the matter; and would he, when introducing the new Housing Bill, include such provisions as would enable local authorities to take over such properties without compensation, and either by restoration or rebuilding make them fit for human habitation.—Sir W. Joynson-Hicks replied: Local authorities already have wide powers under the Housing Acts of acquiring and reconstructing slum properties by means of schemes which as soon as approved by the Minister enable the procedure of the Lands Clauses Acts to be applied. These Acts contain special provisions for dealing with cases where owners of property cannot be found. The question whether further legislation is desirable will be considered in connexion with the new Housing Bill.

Conscientious Objection to Vaccination.

Mr. W. A. Jenkins asked the representative of the Ministry of Health whether, in view of the opinion of the medical profession in favour of vaccination, he would take steps to amend the Vaccination Act so that the power of parent or other person having the custody of a child to make a statutory declaration of conscientious objection to vaccination, as embodied in Section 1 of the Vaccination Act, 1907, should be abolished.—Sir W. Joynson-Hicks replied: It is not proposed to introduce legislation for the amendment of the Vaccination Acts during the present Session.

Appointment of a Medical Officer of Health.

Dr. Watts asked the representative of the Ministry of Health if he intended to sanction the appointment of a medical officer of health which was made by the urban district council of Hindley on Jan. 15th last; if he was aware that, although there were at least 11 applicants holding the diploma of public health, the council selected an applicant who held no diploma nor had had the minimum of experience which was laid down in the Sanitary Officers' Order of 1922 to meet the case of a medical officer of health who, although not having a diploma, had had practical experience of the duties of a medical officer of health, and if he intended to sanction this appointment; and whether he would state his reasons for departing from the general rule laid down in the Sanitary Officers' Order, 1922.—Sir W. Joynson-Hicks replied: The Minister is aware of the facts stated in the question, and has intimated to the Hindley Urban District Council that he is not prepared to approve their selection of a candidate not possessing the required qualifications. The Council have been requested to consider the matter with a view to making a suitable appointment in accordance with the Sanitary Officers' Order, 1922.

Widows and Fatherless Children.

Mr. Rhys Davies asked the representative of the Ministry of Health the number of widows in England, Scotland, and Wales at the last census; and, if possible, the number of fatherless children and orphans under 14 years of age, respectively.—Sir William Joynson-Hicks replied: Figures for England and Wales and Scotland are not yet available for the countries as a whole, but a statement will be sent to the hon. Member when the information is ready. The figures asked for in respect of London, Middlesex, and Herts. are given in the following table:—

—	Widows.	Children under 14.		
		Father dead.	Mother dead.	Both parents dead.
London ..	223,615	80,094	21,533	4,151
Middlesex ..	52,842	19,755	6,302	1,599
Herts	13,977	6,273	1,782	552

A Vaccination Prosecution.

Mr. Lunn asked the representative of the Ministry of Health whether he was aware that the local vaccination officer prosecuted Mr. F. Scholefield, 7, Buckley-road, Cemetery-road, Beeston, Leeds, for not having his child vaccinated; whether the local magistrates made an order on Feb. 15th directing the child to be vaccinated; whether he was aware that the child for which the order was made died on Feb. 24th, after suffering from convulsions through teething; and whether, in view of the danger of vaccination, he would instruct vaccination officers to refrain from prosecuting parents who through no fault of their own had omitted to make a declaration of objection under The Vaccination Act, 1907, within the required period.—Sir William Joynson-Hicks replied: My right hon. friend is not empowered to interfere with the discretion of a vaccination officer in regard to prosecution. He is not aware whether in the case in question the child was unfit for vaccination at the time vaccination was due, but provision is made in the Vaccination Acts for postponement of vaccination in the case of any child who is not in a fit and proper state to be vaccinated. This child was not, in fact, vaccinated, and the certified cause of death was infantile eclampsia.

Unfit Army Recruits in 1922.

Mr. Hancock asked the Under-Secretary of State for War the number of recruits for His Majesty's forces who presented themselves for enrolment during the year 1922, but were rejected as physically unfit to serve, for each town with a population of 100,000 or more.—Lieut.-Col. Guinness replied: I regret that I am unable to give the information requested in a form distinguishing particular towns, but the numbers of recruits who presented themselves in each county recruiting zone in Great Britain for enlistment in the Regular Army during 1922 and the numbers rejected as physically and medically unfit to serve, were as follows:—

Recruiting zone.	Male population.	Numbers presenting themselves for enlistment.	Numbers rejected by	
			Recruiting officers for physical reasons.	Medical officers.
West Surrey ..	213,377	597	97	229
East Kent	215,751	1213	218	277
Royal Fusiliers ..	179,376	1263	487	441

Economy in Public Health Services.

Mr. Alfred T. Davies asked the Chancellor of the Exchequer whether public relief is now being given by seven authorities—viz., employment exchanges for unemployment insurance, boards of guardians, local health authorities, insurance committees, local war pensions committees, local education authorities, and old age pension commitees; and whether the possibility of administering relief through one authority is, or has been, under consideration in view of the waste involved in the present complex system.—Mr. Baldwin replied: If my honourable friend will give me a definition of public relief I will endeavour to answer him, but at present I cannot see why he includes war pensions and excludes civil service pensions, political pensions, and army and navy service pensions, and I am not clear whether he wishes to make a distinction between free health services rendered to individuals and free health services rendered to households, for example the removal of house refuse and sewage. I am also inclined to question the propriety of including normal benefits under State schemes of health and unemployment insurance in the category of public relief.

Registrar-General's Annual Report.

Lieut.-Colonel Fremantle asked the representative of the Ministry of Health if the Registrar-General's annual report for 1921, containing matter of first importance affecting the welfare of the people, would be presented to Parliament.—Sir W. Joynson-Hicks replied: Under the general policy explained in the answer given to Commander Bellairs on May 16th, 1922, this publication, along with others, is now issued as a Stationery Office publication instead of a Command Paper, but this will not interfere with its presentation to Parliament, which is being arranged forthwith.

Thursday, March 8th.

Unemployment and the National Health.

The House went into Committee of Supply on the Civil Service Estimates, Mr. J. F. Hope in the chair.

On a Vote on Account of £126,600,000 for Civil Service and Revenue Departments, Mr. Walsh moved to reduce the vote by £100 on the ground of the inadequacy of the grants given by the Unemployment Grants Committee in aid of relief works started by local authorities.

After some discussion, Mr. Neville Chamberlain, the newly-appointed Minister of Health, who was greeted with general cheers on rising, said he made his grateful acknowledgements to the hon. Members who had made such kindly references to him in the debate. The interest of the Ministry of Health in the subject of unemployment was only second to that of the Ministry of Labour. It was not merely that the prevalence of unemployment meant the infliction of great burdens and liabilities on the boards of guardians and the raising of the rates of local authorities with which the Ministry had to deal, but it affected also the health of the people. The vital statistics of the last few years were a wonderful tribute to the work of the Ministry of Health and the medical officers throughout the country. One would have supposed that the results of unemployment would have been reflected in a great increase in the mortality rate, and especially in the infantile mortality rate; but instead of that they had seen all records broken in the opposite direction. But it would be a mistake to suppose that unemployment did not affect the national health, and in particular the physique of the children. No one who watched the children during the war, when the working classes were earning high wages, could fail to observe the enormous improvement in their appearance. The remarkable figures to which he had alluded might have some foundation in the exceptionally good nourishment which the children were able to obtain during that time. It would be his endeavour, in conjunction with the Minister of Labour, to do all they could to help forward schemes to relieve unemployment. They had, however, to feel their way and proceed from experiment to experiment if they were not to make mistakes which might be disastrous to the finance of the country as a whole. They hoped gradually to build up a system which, though it might never be adequate to cover the whole field, would, as it went on, deal with a gradually increasing proportion of those who were now unemployed and a burden on the rates.

The motion to reduce the vote was rejected by 275 votes to 165, and the vote was agreed to.

Non-Service Doctors on Medical Boards.

Mr. Neil Maclean asked the Minister of Pensions the number of doctors acting on the pensions medical boards who had had no service during the war.—Major Tryon replied: Of some 6000 medical men employed by my department on boarding duties, only 299 (or 5 per cent.) have had no war service. Moreover, the large majority of these are specialists for whom no efficient ex-service substitutes can be obtained.

Fatal Accidents in Mines.

Mr. Tom Smith asked the Secretary for Mines if he would state the total number of persons killed in the mining industry for the 10 years ending 1921; and the total amount of money paid by way of compensation, &c., to their dependents.—Lieut.-Colonel Lane-Fox replied: The total number of persons killed in the mining industry in the United Kingdom during the 10 years ended 1921 was 12,897. Particulars of payments under the Workmen's Compensation Act, 1906, for the years 1915 to 1918 were not collected. In the six remaining years of the period there were 7638 fatal accident cases reported, the total compensation for which amounted to £1,476,062.

Friday, March 9th.

Sale of Intoxicants to Children.

Viscountess Astor, in moving the second reading of the Intoxicating Liquor (Sale to Persons under Eighteen) Bill, said the measure, which was introduced two years ago by the late Lord Bryce, had behind it the teachers and the chief medical authorities in the country. A letter in favour of it appeared in the *Times*, signed by some of the chief figures in the medical profession, and it had the support of *The Lancet* and the *British Medical Journal*. She had personally received 700 letters from medical women approving of it. The Bill proposed to make it illegal to sell to anyone apparently under 18 any kind of intoxicants for consumption in a public-house. It did not touch clubs, because this was not a club problem. The point of the Bill was to help self-control and the powers of resistance. The Bill was just as important for girls as it was for boys. In an official answer given the other day it was stated that in 1919 2610 boys and girls between 16 and 21 were arrested for drunkenness; in 1920 the number was 4063, and in 1921 2172. The chief medical authorities were all at one as to the danger of alcohol in adolescence.

Mr. C. W. Crook, in seconding, said he disliked as much the continued cant of the extremist on one side as he did the continual decant of the extremist on the other. He supported the Bill because alcohol was harmful physiologically and psychologically to the boy and girl.

Mr. Greaves-Lord, who moved the rejection of the Bill, said if it were confined to spirits there might be some degree of unanimity which would render its passage absolutely secure. The real purpose of the Bill—not necessarily the purpose of Lady Astor—was the extension of prohibition into the law of this country.

After considerable discussion, Mr. Bridgeman (Home Secretary) said that as far as the matter affected the Home Office there seemed to be very considerable difficulty in changing the age from 16 to 18. It was far more difficult to distinguish between two boys just under and just over 18 than between boys just under and just over 16. Proceeding to express his personal view, Mr. Bridgeman said that in 1914, out of a total number of convictions for drunkenness of 48,000, there were 2600 people convicted under 21, and probably a much smaller number under 18. In 1920 the numbers rose to 78,000 and 4065. In 1921 they were 64,000 and 2174. That did not show that the young people were growing more intemperate, and it was only fair on their behalf to say that there was no proof that it was a growing evil. If a public-house was properly conducted he should not in the least mind his own boys going in and drinking a glass of beer. Where reform was needed was in the character and atmosphere of the public-house. There was no case to show that beer was bad or unwholesome. If the Bill were confined to spirits, or were restricted to girls, he would take a very different view. How could character be formed unless young people were allowed to meet and overcome these temptations?

On a division the motion for the rejection of the Bill was negatived by 338 votes to 56, and the Bill was read a second time.

Coroner and Death Certificates.

Dr. Chapple asked the Secretary of State for the Home Department whether his attention had been called to the pronouncement of the City coroner that doctors should not sign a death certificate if they had only seen the patient for the first time two hours before death; whether instructions to this effect had been issued by his department; and whether, in view of the fact that such a policy would greatly increase the number of inquests involving post-mortem examinations without adequate justification, he could state the average cost of such inquests.—Mr. N. Chamberlain (Minister of Health) replied: The answer to the first part of the question is in the affirmative. With regard to the second part, no such instructions have been issued by my department or by the Home Office. With regard to the third part I have no information, but will make inquiries and communicate with the hon. gentleman.

Education of Mentally Defective Children.

Mr. Robert Morrison asked the President of the Board of Education how many mentally defective children from London County Council special schools had been returned to elementary schools during the past 12 months; and whether they had been sent to special schools by mistake, or for what reason had they now been returned to elementary schools.—Mr. E. WOOD replied : I am informed that out of about 7000 mentally defective children on the books of special schools in the area of the local education authority for London, 66 were returned to public elementary schools in 1922. It is the practice of all the persons concerned to keep a careful watch over the progress of children in special schools for mentally defective children and to restore to the ordinary public elementary school every child to whom it would be beneficial to pursue his education in normal surroundings. Such restoration does not warrant any inference that an initial mistake was made.

Pension Appeals.

Mr. STEPHEN asked the Minister of Pensions the number of appeals which had been heard by the appeals tribunal until Jan. 31st, 1923 ; and the number of those in which the applicant had had his appeal sustained.—Major TRYON replied : About 99,000 appeals on entitlement have been heard by the Pensions Appeal Tribunal, of which some 27,000 have been decided in favour of the appellant.

Sir EDWIN STOCKTON asked the Minister of Pensions whether he would give the number of cases in which an appellant, having won his appeal to the House of Lords Tribunal, had had the result of such decision negatived by the decision of the medical board to which his case was then referred.—Major TRYON replied : There are no such cases.

MONDAY, MARCH 12TH.

Exhibition of Indecent Films in London.

Mr. NEWBOLD asked the Secretary of State for the Home Department whether his attention had been called to the exhibition of indecent films in London ; and would he explain why effective steps had not been taken to prevent such displays.—Mr. BRIDGEMAN replied : I have seen certain articles in a weekly newspaper to which the hon. Member presumably refers. It is stated in these articles that full particulars have been sent to Scotland Yard, but the Commissioner of Police informs me that no information could be obtained from the newspaper in question which was of the slightest value in leading to the detection of any exhibition of indecent films. The police are fully aware of the danger of such films being exhibited, and will do all they can to provide against it.

Lunacy Act Regulations.

Mr. THOMAS GRIFFITHS asked the Minister of Health whether, in view of the fact that Section 79 of the Lunacy Act conferred upon friends as well as relatives the right to apply to the visiting committee for the discharge of a patient on accepting responsibility in regard to him, and seeing that the plan followed by the asylum authorities of communicating this right by circular to one relative only had the effect of discarding that part of the section which referred to friends, he would take steps to secure that the recommendation of the departmental committee be forthwith carried out and Section 79 be posted up in the waiting rooms of public asylums in order that the rights guaranteed by statute may no longer be intentionally concealed from friends.—Mr. N. CHAMBERLAIN replied : In the opinion of the Board of Control there are serious objections to the general rule requiring that this section should be posted up in waiting rooms. If any friends apply to a mental hospital for a copy of the regulations the Board have no doubt that their request would be complied with. The Board are considering the revision of their rules, and it is proposed to require that copies of regulations as to visitation, which will include the substance of Section 79, shall be sent to all persons mentioned as relatives or friends of the patient in the statement of particulars accompanying the reception order.

The Price of Milk.

Sir JOHN LEIGH asked the Minister of Agriculture whether Lord Linlithgow's Committee would issue an interim report on the price of milk to the consumer ; and, if so, when the report might be expected.—Sir R. SANDERS replied : I understand from the noble marquess, the chairman of the committee to which my hon. friend refers, that a draft report regarding the methods, the costs of selling, and distributing milk is in course of preparation, and that as soon as certain outstanding information has been received it will be completed for presentation.

Meat Inspection.

Mr. TILLETT asked the Minister of Health whether he could inform the House at what date would be issued the proposals to give effect to the recommendations of the departmental committee on meat inspection.—Mr. N. CHAMBERLAIN replied : Effect has already been given to the recommendations of the departmental committee which deal with the question of uniformity in meat inspection by the issue of a circular and memorandum to local authorities in March, 1922. I will send the hon. Member a copy of these documents. Regulations have been drafted to give effect to the committee's recommendations in regard to the marking of meat and these are under discussion with the parties interested. Regulations are also being prepared dealing with the transport and handling of meat, but I am not yet able to say on what date these regulations will be issued.

Medical Officers of Ministry of Health.

Mr. SHORT asked the Minister of Health the number of medical officers now employed in his department and the salaries paid ; and what was the number so employed, and salaries paid, in 1921.—Mr. N. CHAMBERLAIN replied : The number of medical officers now employed by the Ministry of Health is 56, and their salaries, including bonus, amount to £62,504. In addition there are 35 regional medical officers employed, whose salaries amount to £16,125, which sum is now recovered from the approved societies. In March, 1921, the medical staff of the Ministry, including the regional medical staff, was 101, whose salaries, including bonus, amounted to £130,630, the whole payable from executive funds.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY, Burlington House, London, W.

THURSDAY, March 22nd.—4.30 P.M., *Papers to be read* :—G. Hewett : The Dusuns of British North Borneo. (Communicated by W. B. Hardy, Sec. R.S.) L. T. Hogben and F. R. Winton : The Pigmentary Effector System. III. Colour Response in the Hypophysectomised Frog. (Communicated by Prof. E. W. MacBride.) H. R. Hewer : Studies on Amphibian Colour Change. (Communicated by Prof. E. W. MacBride.) J. Walton : On Rhexoxylon, Bancroft. A Triassic Genus of Plants Exhibiting a Liane-type of Vascular Organisation. (Communicated by Prof. A. C. Seward.)

Papers to be read in title only :—Margaret Tribe : The Development of the Hepatic Venous System and the Postcaval Vein in the Marsupialia. (Communicated by Prof. J. P. Hill.) J. Gray : The Mechanism of Ciliary Movement. III. The Effect of Temperature. (Communicated by Prof. J. S. Gardiner.) E. Ponder : The Inhibitory Effect of Blood Serum on Hæmolysis. (Communicated by Sir E. Sharpey Schafer.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Tuesday, March 20th.

GENERAL MEETING OF FELLOWS : at 5 P.M. Ballot for election to the Fellowship.

PATHOLOGY : at 8.30 P.M.

Annual General Meeting :

Election of Officers and Council for 1923–24.

Papers :

Dr. S. C. Dyke : Preliminary Communication on Some Tumours Containing Anisotropic Fatty Bodies.

Mr. A. G. Timbrell Fisher : The Nature of Osteo-Arthritis as Revealed by an Investigation into the Earlier Pathological Changes.

Demonstration :

Dr. E. H. Kettle : Lipoid Degeneration of the Kidney.

Wednesday, March 21st.

HISTORY OF MEDICINE : at 5 P.M.

Papers :

Mr. R. R. Steele : Chemical Knowledge of the Thirteenth Century.

Mrs. Singer : Some Quips and Cranks of a Mediæval Alchemist.

Social Evening.

The last Social Evening of the Session will be held on Wednesday, March 21st, at 8.30 P.M.

Fellows, Members of Sections, Associates, and their friends will be received by the President, Sir William Hale-White, and Lady Hale-White, at 8.30 P.M.

Dr. H. C. Cameron will deliver a short (illustrated) Address at 9 P.M. on the Mystery of Lord Byron's Lameness.

The Library will be open and various objects of interest will be exhibited. Music, light refreshments, and smoking.

LIBRARY : On this evening the principal Reading Room will be closed at 5 P.M., but readers will be accommodated in other rooms.

Thursday, March 22nd.

UROLOGY : at 8.30 P.M.

Paper :

Mr. Swift Joly : Diverticulum of the Bladder with Special Reference to Operative Treatment.

Friday, March 23rd.

STUDY OF DISEASE IN CHILDREN : at 5 P.M. (Cases at 4.30 P.M.)

Cases : The following will be shown by :—

Dr. Parkes Weber : A Case of Raynaud's Syndrome.

Dr. G. M. Kendall : A Case of Patent Ductus Arteriosus.

Dr. Cautley : A Case of Rickets.

Dr. R. C. Jewesbury and Mr. C. Max Page : Two Cases of Duodenal Obstruction in Infants.

Dr. Mandel: A Case of Tay-Sachs's Disease.
Dr. C. Worster-Drought: A Case of Enlarged Liver with Persistent Acetonuria.

EPIDEMIOLOGY AND STATE MEDICINE: at 8 P.M.
Paper:
Mr. N. Bishop Harman: Surface Diseases of the Eye in their Epidemiological Aspects.

MEDICO-LEGAL SOCIETY, 11 Chandos-street, Cavendish-square, W.
Tuesday, March 20th.—8.30 P.M., Dr. H. A. Burridge: State Effort to Rescue Drug Victims, with Special Reference to the Dangerous Drugs Act. (To be followed by a discussion.)

ROYAL SOCIETY OF ARTS, John-street, Adelphi, London, W.C. 2.
Wednesday, March 21st.—8 P.M., Dr. F. W. Edridge-Green: Some Curious Phenomena of Vision and their Practical Importance. The paper will be illustrated with lantern and other demonstrations. Prof. E. H. Starling will preside.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

ROYAL COLLEGE OF PHYSICIANS OF LONDON, Pall Mall East, S.W.
Tuesday, March 20th.—5 P.M., Second Lumleian Lecture:—Dr. A. J. Hall: Encephalitis Lethargica (Epidemic Encephalitis).
Thursday.—5 P.M., Third Lumleian Lecture.

FELLOWSHIP OF MEDICINE, POST-GRADUATE LECTURES, 1, Wimpole-street, W.
Thursday, March 22nd.—5.30 P.M., Dr. H. W. Barber: The Investigation of Certain Diseases of the Skin in the Light of Recent Research.

WEST END HOSPITAL FOR NERVOUS DISEASES.
The following Clinical Demonstrations will be held during the forthcoming week in the Out-patient Department of the Hospital, 73, Welbeck-street, W. The Demonstrations are open to Practitioners and Medical Students without fee.
Thursday, March 22nd.—4.30 P.M., Dr. Hildred Carlill: Practical Points in Everyday Neurology.
Friday, March 23rd.—1.30 P.M., Sir James Dundas Grant: Nerve Deafness.
C. Worster-Drought, M.D., Dean.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.
Monday, March 19th.—10 A.M., Mr. MacDonald: Genito-Urinary Department. 12 noon, Mr. Simmonds: Applied Anatomy. 2 P.M., Mr. Addison: Surgical Wards.
Tuesday.—10.30 A.M., Dr. Paterson: Demonstration of Medical Cases. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.
Wednesday.—11 A.M., Mr. Simson: Gynæcological Demonstration. 12 noon, Dr. Burnford: Pathological Demonstration. 3 P.M., Dr. Pernet: Skin Department.
Thursday.—10 A.M., Dr. Grainger Stewart: Neurological Department. 12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Bishop Harman: Eye Department.
Friday.—12 noon, Dr. Flett: Radiology. 2 P.M., Mr. Banks Davis: Diseases of Nose, Throat, and Ear. 3 P.M., Mr. Sinclair: Surgical Cases.
Saturday.—9 A.M., Dr. Burnford: Bacterial Therapy. 10 A.M., Dr. Saunders: Medical Diseases of Children. 10.30 A.M., Mr. Maingot: Surgical Pathology.
Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M., In-patients, Out-patients, Operations, Special Depts.

SOUTH-WEST LONDON POST-GRADUATE ASSOCIATION, St. James's Hospital, Ouseley-road, Balham, S.W.
Wednesday, March 21st.—4.30 P.M., Dr. C. E. Lakin: Demonstration of Medical Cases.

NATIONAL HOSPITAL FOR THE PARALYSED AND EPILEPTIC, Queen-square, Bloomsbury, W.C. 1.
POST-GRADUATE COURSE: Jan.–March, 1923.
Clinical Lectures and Demonstrations.
Monday, March 19th.—2 P.M., Out-patient Clinic: Dr. Hinds Howell. 3.30 P.M., Lecture:—Involuntary Laughing and Crying: Dr. Kinnier Wilson.
Tuesday, March 20th.—2 P.M., Out-patient Clinic: Dr. Grainger Stewart. 3.30 P.M., Lecture:—Subacute Combined Degeneration of Spinal Cord: Dr. Hinds Howell.
Thursday, March 22nd.—2 P.M., Out-patient Clinic: Dr. Kinnier Wilson. 3.30 P.M., Demonstration in Exercise Room on Methods of Re-education of Movements.
Friday, March 23rd.—2 P.M., Out-patient Clinic: Dr. Gordon Holmes. 3.30 P.M., Demonstration in Exercise Room on Methods of Re-education of Movements.
Mr. Armour and Mr. Sargent operate at the Hospital on Tuesday and Friday mornings at 9 A.M., or at such other times as may be announced.
Neuro-Pathology.
Monday, March 19th.—12 noon, Tumours of the Nervous System: Dr. J. Godwin Greenfield.
Fees should be paid to the Secretary of the Hospital at the office on entering for the Course.
C. M. Hinds Howell, Dean of Medical School.

NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, Marylebone, W. 1.
Thursday, March 22nd.—Dr. J. Strickland Goodall: The Toxic Heart.

LONDON HOSPITAL MEDICAL COLLEGE, Turner-street, Mile End, E. (Anatomical Theatre).
Monday, March 19th (and the two following days).—4 P.M., Dr. Otto F. F. Leyton: Diabetes Mellitus.

HOSPITAL FOR SICK CHILDREN, Great Ormond-street.
Thursday, March 22nd.—4 P.M., Dr. Thompson: Choreas.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.
Thursday, March 22nd.—5 P.M., Dr. J. B. Banister: Obstetric Emergencies.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSES.
Tuesday, March 20th.—4.15, Mr. J. P. Buckley: Intussusception.
Friday.—Mr. W. R. Douglas and Dr. J. M. W. Morison: The Diagnosis and Surgical Treatment of Lesions of the Large Intestine.

SALFORD ROYAL HOSPITAL POST-GRADUATE LECTURE.
Thursday, March 22nd.—4.30 P.M., Mr. Jefferson: Some Points in the Surgery of the Spine. *Unavoidably postponed.*

ROYAL INSTITUTE OF PUBLIC HEALTH, 37, Russell-square, W.C.
Wednesday, March 21st.—4 P.M., Dr. W. J. O'Donovan: The Industrial Menace of Syphilis.

Appointments.

Allan, G. G., M.B., Ch.B. Edin., D.P.H. Edin., has been appointed Clinical Pathologist to the Crichton Royal, Dumfries.

Martin, A. A., M.D. Lond., one of the Medical Referees under the Workmen's Compensation Act for County Court Circuit 50, Eastbourne, &c.

Murdoch, Georgina, M.B., Ch.B. Glasg., Assistant School Medical Officer at Wigan.

Walker, G. C., M.D., Ch.B. Manch., Medical Officer of Health for Lythom, St. Anne's.

Surgeons under the Factory and Workshop Acts: Clark, W. H., M.D. Aberd. (Bucksburn, Aberdeen); Steele-Perkins, D. S., L.R.C.P. & S. Edin., L.R.F.P.S. Glasg. (Honiton).

Vacancies.

For further information refer to the advertisement columns.

Bedford County Hospital.—H.S. and Asst. H.S. £175 and £130 respectively.

Birmingham and Midland Homœopathic Hospital and Dispensary.—Res. H.S. £175.

Birmingham and Midland Hospital for Skin, &c., Diseases.—Asst. Radiologist.

Birmingham Orthopædic Centre.—Jun. M.O. £350.

Blackwell and Skegby Rural District Councils and the Derbyshire County Council.—M.O.H. £800.

Bristol Royal Hospital for Sick Children and Women.—Hon. S. to Out-patients.

Central London Ophthalmic Hospital, Judd-street, St. Pancras. W.C. H.S. £100. Jun. H.S. £50. X ray O. and Asst. S.

Chester Royal Infirmary.—Asst. H.S. £150.

Coventry and Warwickshire Hospital.—Res. H.P. £200.

Croydon General Hospital.—Jun. H.S. £150.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Anæsthetist. £50.

Elizabeth Garrett Anderson Hospital, Euston-road.—Asst. M.O. to V.D. Dept. £1 1s. per attendance. Also Asst. P. to Out-patients.

Evelina Hospital for Children, Southwark, S.E.—Hon. P. Hon. Dental S.

Gloucestershire Royal Infirmary and Eye Institution.—Surg.

Halifax Royal Infirmary.—Third H.S. £150.

Hospital for Sick Children, Great Ormond-street. W.C.—H.P. £50. Also Surg. Registrar. £300.

Lagos Town Council, Africa.—Asst. M.O.H. £750.

Leicester, North Evington Poor-law Infirmary.—Res. M.O. £300.

Lincoln, Lindsey County Council.—Asst. Tub. O. and Asst. School M.O. £500.

Liverpool Open Air Hos. for Children, Leasowe.—Jun. M.O. £250.

Liverpool, Royal Southern Hospital.—Hon. P.

London Fever Hospital, Islington, N.—Hon. Aural S.

London Lock Hospital, 91, Dean-street. W.—H.S. £200.

Manchester, Christie Hospital for Cancer.—M.O. and Reg. £120.

Manchester Royal Eye Hospital.—H.S.

Manchester, Victoria Memorial Jewish Hospital, Cheetham.—R.M.O. £150.

Newcastle-upon-Tyne, Royal Victoria Infirmary.—H.P.'s and H.S.'s. Each £50, except H.S. to Out-patients, £100.

Paddington Green Children's Hospital, W.—H.P. and H.S. Each £150.

Prince of Wales's General Hospital, Tottenham, N.—H.P. and H.S. Each £150. Jun. H.S. and Jun. H.P. Each £110.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Cas. H.S., Two H.P.'s, and H.S. Each £100. Also Asst. P. £1 1s. per attendance.

Rotherham Hospital.—Jun. H.S. £150.

Royal Free Hospital, Gray's Inn-road, W.C.—Cas. O. £100.

Royal National Orthopædic Hospital, 234, Great Portland-street, W.—H.S. £150.

St. Mark's Hospital for Cancer, &c., City-road, E.C.—H.S. £200.

Seamen's Hospital Society, Dreadnought Hospital, Greenwich, S.E.—H.S. £150.

Sheffield, South Yorkshire Asylum.—M.O. £400.
Smethwick, Cornwall Works Dispensary.—M.O. £600.
South London Hospital for Women, Clapham Common, S.W.—H.P. £100.
Truro, Royal Cornwall Infirmary.—H.S. £170.
University College Hospital, Gower-street, W.C.—Clin. Asst. for Ear, Nose, and Throat Dept. House Anæsthetist. £150. Also Hon. Ophthalmic S.
University College Hospital Medical School, University-street, W.C.—Asst. to Professor of Pathology. £500.
Wakefield, Middleton-in-Wharfedale Sanatorium, near Ilkley.—Res. Asst. M.O. £325.
West End Hospital for Nervous Diseases, 73, Welbeck-street, W.—Hon. Registrar.
Western Australia Lunacy Dept.—Jun. A.M.O. £432.
Western Ophthalmic Hospital, Marylebone-road, N.W.—Hon. Asst. S. 100 guineas.
West London Hospital, Hammersmith-road, W.—H.P. and Two H.S.'s. Each £100.
Westminster Hospital.—Asst. M.O. to Elec. Dept. £200.
Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

The Chief Inspector of Factories, Home Office, London, S.W., announces the following vacant appointment: Walton-on-Naze (Essex).

Births, Marriages, and Deaths.

BIRTHS.

JEPSON.—On March 6th, at Longridge-road, Earl's Court, S.W., the wife of Dr. W. B. Jepson, M.C., of a daughter.

MEREDYTH JONES.—On March 2nd, 1923, at Croydon, to Muriel, the wife of C. Meredyth Jones, F.R.C.S.—a daughter.

PETTY.—On March 7th, at St. Mary Bourne, near Andover, Hants, the wife of Dr. David Petty, of a son.

RICHARDSON.—On March 10th, at Belgrave-road, S.W., the wife of Captain D. T. Richardson, M.C., R.A.M.C., of a son.

ROBERTS.—On March 10th, at Oak-road, Woolston, Southampton, the wife of Dr. P. M. Roberts, of a son.

WEBSTER.—On Feb. 24th, at Holcombe, near Bath, the wife of Francis Webster, L.R.C.P. & S.I., of a son.

DEATHS.

DALTON.—On March 9th, at Fellows-road, Hampstead, Norman Dalton, M.D., F.R.C.P., late Senior Physician to King's College Hospital, aged 65.

MEREDYTH JONES.—On March 9th, 1923, at Croydon, Muriel, the wife of C. Meredyth Jones, aged 27 years.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

THE USE OF SALINE SOLUTIONS INTRAVENOUSLY.*

BY SIR W. M. BAYLISS, F.R.S.,
PROFESSOR OF GENERAL PHYSIOLOGY, UNIVERSITY COLLEGE, LONDON.

As is indicated by the title of my remarks, they will be limited to the discussion of artificial solutions. It will, however, be necessary to refer incidentally to some properties in which they are comparable with blood as used for transfusion. We have first to remember that such artificial solutions merely increase the volume of the blood in circulation without adding to its important constituents. We may ask: What, then, is their value?

To begin with the foundations of the problem. It is scarcely necessary to point out that the tissues need a continual supply of certain things which we call, in general terms, "foods," of which the most vital is oxygen. This is carried by the red blood corpuscles, and must be afforded at a certain minimal rate if the cells are to be preserved from the effects of want of oxygen. Thus, if the blood is diluted, it must be sent at a faster rate to make up for the lower concentration in corpuscles. Now when the total volume of the blood is deficient the blood pressure is low because the heart does not receive enough by the veins to send on. Hence the tissues actually do suffer from want of oxygen, although the blood may be of normal constitution. Looked at in another way—at the moment of systole the ventricles contain a certain fraction of the whole blood; hence, if this is smaller than the normal amount, the ventricles can only propel in unit time less than they should do. The amount flowing through any particular vascular region is therefore diminished.

When the volume of the blood is brought up to its normal value by the addition of an indifferent fluid a much larger volume circulates. Although this diluted blood does not contain so large a percentage of corpuscles as that which was circulating very slowly before the injection, it has been found by experiment that the greater rate of supply much more than compensates for the dilution. In other words, the number of corpuscles passing a particular cell in unit time is greatly increased and the supply of oxygen becomes sufficient. This is briefly the justification for the use of intravenous injections. The incidental rise of blood pressure is of subsidiary importance. Such a rise can be effected by adrenalin, but only at the cost of restricting the supply of blood to the larger number of organs.

An interesting question arises as to how far the decrease of corpuscles can be effectively replaced in the way described. From experiments on animals it appears that the number of corpuscles in the body may be reduced by hæmorrhage to one-third or less. This would mean an enormous loss of blood in man.

The Nature of the Solution Used.

We may consider the nature of the solution to be used. In theory, of course, blood itself seems the obvious thing to replace blood which has been lost, except perhaps in traumatic shock without loss of blood, where the corpuscles are merely stationary in the capillaries until carried again into the effective blood-stream. But in any case, blood is not always available at a moment's notice, and there are cases where prompt action is of vital importance. Physiological saline (0·9 per cent. sodium chloride in water) was naturally the first solution to be tried. It was known to be innocuous, and had been found effective for isolated organs and for the preservation of blood corpuscles. But it was found useless for replacing lost blood in the whole organism. Measurements showed that it had disappeared from the circulation in 20 to 30 minutes or less. Why is this the case? Here we cannot avoid referring to the difficult question of *osmotic pressure*. With regard to the explanation of the way in which osmotic pressure is produced even experts are not agreed. Thus we must be content with a brief consideration of the facts. Suppose that we have a bag of a material, such as parchment paper or collodion, which is pervious to water, but whose pores, although large enough to allow salts and sugar to pass through, are too small for the large particles of colloids, such as the proteins of the blood. Let us fill this sac with blood and immerse it in water. The salts soon pass through and becoming practically equal on both sides may be neglected for our present purpose. But the colloids remain inside. This difference between inside and outside causes in some way the attraction of water to the interior. The force of this attraction is proportional to the concentration of the colloids and in normal blood is of the value of 35 to 40 mm. of mercury pressure. This is known as the osmotic pressure of the blood colloids. If we put pressure on the contents of the sac so as to try to force water out of the sac by filtration, none will escape until the pressure applied exceeds the opposing osmotic pressure of the contents of the sac.

---

* Lecture given at the Children's Clinic, Marylebone-road, London, on March 6th, 1923.

The walls of the blood-vessels, in so far as we are concerned with their permeability, have properties like those of parchment paper and normally do not allow passage to colloids. Hence the conditions are present for these colloids to exert their osmotic properties of attracting water with a certain force. But in the arteries and the first part of the capillaries the blood pressure is higher than this. There is accordingly filtration of fluid (= lymph). As we proceed towards the veins, the blood pressure diminishes and reaches a value below that of the osmotic pressure of the blood colloids. Reabsorption begins here and most of the previous filtrate is taken back again. What remains is carried to the thoracic duct by the lymphatic vessels.

We have seen that the value of the osmotic force is proportional to the concentration of the colloids in the blood. Hence, if we dilute the blood by the addition of a solution which contains no colloids, we reduce the force opposing filtration and the blood has also to travel further along the capillaries before the blood pressure is reduced sufficiently to allow reabsorption. Both causes combine to produce an excessive filtration, which will continue until the blood returns to its normal osmotic pressure—that is, until the liquid injected has disappeared.

The obvious conclusion is that some colloid with an osmotic pressure equal to that of the blood colloids must be added to our injection solution. What are the colloids which it is possible to use? Serum proteins from foreign sources cause hæmolysis and anaphylaxis. Gelatin serves well, but is liable to contain tetanus spores and may cause trouble by setting to jelly in the tubes of the apparatus. On the other hand, gum arabic or acacia answers all requirements. It is quite innocuous and in a concentration of 6·5 to 7 per cent. in 0·9 per cent. sodium chloride has an osmotic pressure equal to that of the colloids of the blood. Its viscosity also is practically identical with that of the blood, although this is not of great importance. The salt is necessary because the blood corpuscles and tissue cells are impermeable to salts, hence their osmotic pressure must be balanced. Such solutions have in practice been found to cause a permanent increase in the volume of the blood. An essential point is that the gum must be good, in clear nearly colourless lumps, such as is sold as "Turkey elect." Powdered samples seem to be adulterated. At the instance of the Medical Research Council, Messrs. Evans, Lescher, and Webb supply a sterilised solution ready for use. Messrs. Martindale prepare a concentrated solution for dilution as required. It is to be noted that the heating in an autoclave reduces the viscosity somewhat. Thus the rise of blood pressure produced by a given volume is not so great as with the full viscosity. But this may be an advantage, since it reduces the work of the heart.

The Indications for Intravenous Injection.

Passing on to the conditions in which intravenous injection may be of value, we may call to mind the several ways in which the volume of the blood in actual circulation may be reduced. By actual hæmorrhage from wounds or post-partum; by great loss of water from the intestine, as in cholera, infantile diarrhœa, &c.; by dilatation of the capillaries and stasis therein, as in traumatic shock. In operations, hæmorrhage and shock may combine and gum saline should always be ready for use. It has been found of much value in this way at the Women's Hospital in New York. It is rather remarkable that it has the property of restoring the renal function in blackwater fever, probably by raising the blood pressure. After hæmorrhage the rate of formation of new blood corpuscles is hastened. It is likely that this depends on a due supply of blood to the bone marrow.

Certain objections have been made to gum saline. It is sometimes ineffective, as in severe traumatic shock. In this state the capillaries have become permeable even to the colloids of the blood and transfusion of blood itself is useless, as was found in the casualty clearing stations in the war. Experiments on animals suggest, however, that repeated small doses may restore otherwise hopeless cases. When no blood has been lost, and the reduced volume is due to stasis in the capillaries, it would seem reasonable that a further supply of corpuscles is not needed, provided that those in a stationary condition can be washed into the circulation. So-called "chills" have been met with, but not more frequently than with blood or simple saline. Agglutination of corpuscles occurs in the cat, but does not appear to be present in man. It is harmless, even in the cat—a deposit of agglutinated corpuscles can be injected and is at once resuspended. There is no hæmolysis.

Misstatements are often made. Prejudice attributes anything that happens after a gum infusion to its use. A case came under my notice in which it was stated that capillary embolism had been produced by gum. On looking up the notes of the autopsy, it was found that there was nothing of the kind, and indeed nothing pathological that could be attributed to the gum. The possibility of unpleasant feelings during recovery of the nerve centres from their anæmia is not to be overlooked. The indication is to inject slowly.

In conclusion, an interesting physiological state may be referred to in which neither blood nor gum saline causes more than a brief rise in blood pressure. This is the low blood pressure resulting from section of the spinal cord just below the bulb. No explanation has been found for the fact.

PUBLIC HEALTH IN CALCUTTA.*

THE total population of the city of Calcutta was found to be 896,067 at the census of 1911, males numbering 607,674 and females 288,393; and on these figures the statistics are calculated for 1920. Hindus numbered 606,382 and Mohammedans 241,587, and of the remainder 27,659 were non-Asiatics and Anglo-Indians. The general death-rate was 39·3 per 1000 in 1920, being a slight improvement on that of the previous year (42·2), but considerably above that of the preceding quinquennium (30·8); for the three years, 1918–20, the average was 38·8, as compared with 25·6 for the previous three years—that is, since influenza swept through the city in 1918 the ratio has risen by 50 per cent.; Bombay and Madras, however, had higher ratios (46·80 and 41·30 respectively). The medical officer of health, Dr. H. M. Crake, considers that the high ratio, especially from "all other causes," appears to be indirectly due to the repeated epidemics of influenza, and the resultant lowering of vitality and diminution in the power of resisting disease. "All classes of the community, whether living in the slums which, in Lord Curzon's famous phrase, 'skulk behind a fringe of palaces,' or in the 'palaces' of the first-class residential areas, suffered to a greater or less extent." Every ward in the city returned deaths greatly above the average. In the various wards the mortality ranged from 15·4 per 1000 in Park-street, 18·2 in Bamun Bustee, and 20 in Waterloo-street, to 54·3 in Entally and 76·8 in Kidderpore. The death-rate among males was 33·8, while among females it was 50·9. Hindus had a mortality of 41·4, Mohammedans 37·1, and "non-Asiatics and Anglo-Indians" 26·2 per 1000. Dr. Crake draws attention to the high female mortality between 15 and 40 years of age, as compared with that of males in the corresponding periods; the ratios for the year were, for males, 15·0, 17·6, and 22·4 per 1000 for ages 15–20, 20–30, and 30–40; while for females the corresponding ratios were 27·9, 28·9, and 30·8. The chief diseases causing this excess female mortality were tuberculosis (3·6 per 1000), respiratory diseases (11·4), dysentery and diarrhœa (4·8), and malaria (2·0); the corresponding male mortality ratios being 1·7, 7·9, 2·8, and 1·2. This heavy incidence of tuberculosis among females is intimately associated with the *purdah* system: "in order to secure privacy the zenana is inevitably the darkest and worst ventilated portion of the house, as it must be screened from observation on all sides."

The infantile mortality (386·0 per 1000 births) was higher than in the previous year (357·8), and much in excess of the years immediately preceding, 249·1, 239·2, and 280·5 in 1916–17–18; it was higher than in any year since 1902; but Dr. Crake considers that this increase is largely due to defective birth registration in the last two years; in Fenwick Bazar Ward (No. 13) the birth-rate declined from 6·8 in 1919 to 5·2 in 1920, the infantile mortality ratio rising from 450 to 786 per 1000 births; in Bow Bazar Ward (No. 10) the birth-rate fell from 12·7 to 8·1, while the mortality rose from 438 to 637 per 1000 births; in Collinga Ward (No. 15), where the birth-rate fell from 13·6 to 10·1, the mortality rose from 380 to 617 per 1000 births. "It is all very baffling, and it seems to be of very little use trying to make any general deductions from these data." But it is clear that it is the urban wards that have the highest ratios; "babies have a very poor chance of surviving in the slums of Bara Bazar." Of the total 5935 infantile deaths, 1798 (30 per cent.) occurred during the first week of existence; the chief causes were debility at birth (854), premature birth (508), and tetanus neonatorum (335). From one week to one month there were 900 deaths (15 per cent. of total), of which 436 were from tetanus. This is due to "dirty midwifery," and is absolutely unknown among cases attended by the municipal midwives. Among Mohammedans the infantile mortality was 449, and among Hindus 381 per 1000, the ratio for non-Asiatics and Anglo-Indians being 227, and the same for native Christians. The high rate for Mohammedans is due to the *purdah* system and to the neglect of medical attendance; it is surprising to find the same ratio applicable to both Anglo-Indians and native Christians, especially as the general mortality ratios were 26·2 and 34·8 respectively.

---

* Calcutta: Corporation Press, October, 1921.

Causes of Death.

Only 53 deaths were recorded from *plague* during 1920, giving a ratio of 0·05 per 1000, as compared with 0·37 in 1919; of the 57 cases, 53 were fatal, all except three occurring among Hindus; it is noted, however, that not a single death was returned among Mohammedan females, which suggests concealment of cases; 54 out of the 57 were of the bubonic type. *Cholera* caused 2302 deaths (2·6 per 1000, as compared with 4·1 in 1919); it began later than usual, reached its maximum in June, when there were 386 deaths, declined to 50 deaths in September, but rose again to 210 in November. The wards most affected were Coomartoli (3·8 deaths per 1000), Kidderpore (3·6), Watgunge and Garden Reach (3·6), and Jorabagan (3·4), all of these being riparian sections, either on the Hooghly, or Tolly's nullah, or near the docks. "The use of unfiltered water for domestic purposes, particularly during the hot weather, when the supply of filtered water (largely owing to the appalling amount that is wasted) is insufficient, is responsible for many cases of cholera. This appears to explain the high rate of mortality in Kidderpore, a great deal of which occurred amongst the large cooly population." Contamination of food by dust and flies is another important source of infection, as there are still thousands of service privies remaining in the city. Among Hindus the death ratio was 3·3 per 1000, for Mohammedans 1·1, for Indian Christians 1·2, and among non-Asiatics and Europeans only 0·36.

Small-pox, which had caused 1870 deaths (2·1 per 1000) in 1919, became truly epidemic in 1920, when the deaths numbered 2925 (3·3 per 1000), this ratio being higher than in any year of the present century except 1906 (3·4) and 1909 (4·4); the wards that suffered most were Entally (6·2) and Mocheepara (5·6). For Hindus the death-rate was 3·6, and for Mohammedans 2·7; while among non-Asiatics and Anglo-Indians the mortality was only 1·5, and among Indian Christians 1·4 per 1000. For all classes combined the female mortality was 4·1, as compared with 2·9 for males. Amongst infants and children up to 5 years of age the deaths numbered 1115, being 38 per cent. of the total small-pox mortality, exactly the same proportion as in 1919; this "seems to indicate that a large number of children are unvaccinated," and this was found to be the case in Ward 14 (Taltollah). Dr. Crake emphasises the vital importance of revaccination in the tropics; "in fact it is hardly an exaggeration to say that in the tropics primary vaccination cannot be relied upon as a preventive of small-pox. In many cases it merely gives temporary protection." The phrasing of this opinion is rather unfortunate, and antivaccinators may not improbably quote the first clause as an argument against the necessity for vaccination in toto, which, of course, is the very reverse of Dr. Crake's intention. Later on Lieut.-Colonel A Leventon, I.M.S., superintendent of the Campbell Hospital, states distinctly that "the onus falls on each and every person to be protected by vaccination and revaccination, and as the operation need not cause hardly a moment's discomfort it is folly to be unprotected; and it may be necessary at no distant date to penalise those people who have gone through an attack of small-pox, whereby, by reason of their slackness or perversity, they have become a charge and a burden on the State, and the parents of children suffering from the disease should be cited before a magistrate for disciplinary measures." This *argumentum ad crumenam* is perfectly sound, and may appeal to persons who are unable to appreciate (or understand) the value of vaccination. The accommodation available was taxed to the utmost, but the emergency was satisfactorily met by the energy of the medical and nursing staff. Lieut.-Colonel Leventon states that "no case of small-pox was refused admission to hospital"; at this hospital, with a nominal bed-strength of 164, as many as 240 patients were under treatment at one time; additional accommodation was found by erecting sheds for convalescents.

The recorded deaths from enteric fever numbered 360 giving a ratio of 0·40 per 1000, compared with 0·44 in 1919, and higher than any year in the quinquennium (1915–19); it prevailed throughout the year, being most fatal in May, September, and October, when the deaths numbered 42, 38, and 42. In Wards Nos. 4 (Sookeeas-street) and 22 (Bhowanipur) the death ratios were 0·74 and 0·73 per 1000; in No. 24 Ward (Kidderpore and Ekbalpur), which has the highest *total* mortality ratio (76·8) in the whole city, the enteric death ratio was only 0·04, being lower than in any other ward except Hastings, the only one where there were no deaths from this disease. Dr. Crake considers that enteric is not, to any great extent, a waterborne disease in Calcutta, but that infection is chiefly caused through "carrier cases." The enormous difference between the mortality ratios in Mohammedans (0·08), Hindus (0·50), and Indian Christians (1·2) is noteworthy. Among non-Asiatics and Anglo-Indians the ratio was 0·61 per 1000.

Malaria caused 1289 deaths (1·4 per 1000), the ratio being somewhat higher than in any year since 1915, when it had been the same. The greatest prevalence was recorded in the adjoining Wards 11 and 14 (Puddopooker and Taltollah), 2·9 and 2·8 per 1000; but if "other fevers" are combined with "malaria" deaths, the total ratio for the city becomes 3·7, and the wards most affected Nos. 21 (Ballygunge and Tallygunge) with 6·1; and No. 14 (Taltollah) with 5·9 per 1000. Undiagnosed influenza probably accounted for a great deal of the "fever" mortality in the non-malarious wards, but "all over the city there are thousands of potential, if not actual, breeding places for mosquitoes: in some parts 60 per cent. of the reserve tanks examined contained anopheles larvæ." Mohammedans had a fever mortality-rate of 2·9, while for Hindus the ratio was only 0·95 per 1000; among Indian Christians the ratio was 0·50, and for non-Asiatics and Anglo-Indians only 0·32 per 1000. Under the heading of "Other fevers" the mortality was considerably greater than for malaria, the total deaths numbering 2065, giving a ratio of 2·3 per 1000; the wards most affected were Entally (5·5), Ballygunge (4·8), and Hastings (4·3).

"One of the few satisfactory features in the vital statistics for 1920 is the decline in mortality from diarrhœal diseases"; the ratio fell from 3·9 to 3·5 per 1000; in Park-street Ward it was only 0·94, and in Bamun Bustee 0·96; in Kidderpore it was 7·5, and in Bhowanipore 6·3. The excess in the wards named was probably due (at any rate in part) to the inadequate supply of filtered water in the south of the city, owing to the waste that occurs in the northern wards. An increase has to be recorded in mortality from tuberculosis, the death ratio being 2·4, compared with 2·1 per 1000 in 1919; this has been due to influenza, or post-influenza debility, diminishing resistance to infection; 2022 out of 2120 cases were pulmonary, infection having probably been spread directly or indirectly through sputum. The highest death ratios occurred in Wards 20 (Baniapooker) and 21 (Ballygunge), where the mortality was 3·6 and 3·3 per 1000—both these wards are "suburban": "a dark, damp, ill-ventilated hut in an open suburb is evidently just as deadly as a badly lighted and ventilated room in the heart of the city." Dr. Crake strongly emphasises what he considers to be "the most striking figures in the whole of the vital statistics": the death-rate from tuberculosis among females was 3·6, among males 1·7 per 1000. In the age-group 10 to 15 years the male death ratio was 0·32, that for females 2·1; from 15 to 20 years, the ratios were 1·3 and 6·5; from 20 to 31 years, 1·7 and 5·9. "For every boy that dies of tubercle six girls die; for every young man that dies of tubercle five young women die." The chief cause of this "appallingly high rate" amongst females is, of course, the *purdah* system. The zenana is almost invariably in the inner portion of the house, ill-lighted and ill-ventilated, but effectually screened from observation.

Respiratory diseases caused 9·1 deaths per 1000, as compared with 9·2 in the previous year. In Kidderpore ward the ratio was extremely high, 35·6 per 1000; a considerable proportion of deaths must have been due to influenza; but this ward always has a high mortality, largely due to defective drainage and flooding during heavy rain. There was a marked fall in influenza mortality (as recorded), 1·8 compared with 3·7 per 1000 in 1919; in Alipore Ward the ratio was 3·1. Dr. Crake acknowledges that any accurate estimate of the number of deaths from influenza is impossible, but considers the actual mortality to have been about 5000, compared with an estimated 7000 in each of the two years preceding. Relief centres were kept open in all badly-infected areas. Epidemic dropsy caused 112 deaths, compared with 96 in 1919; the outbreak prevailed chiefly during January, February, and March, when 67 out of the 112 deaths occurred; it was most severe in Wards 3, 4, and 6 (Burtollah, Sookeas-street, and Jorasanka) in the north, and Ward 25 (Watgunge and Garden Reach) in the south; females suffered much more than males (0·25 and 0·06 deaths per 1000 respectively). Dr. Crake considers that there is no doubt that it is a specific infectious disease; the high percentage of cases with gastro-intestinal symptoms seems to indicate infection through the gastro-intestinal tract. The intense local house infection, its spread through the agency of human beings, but not from man to man, its sudden appearance and disappearance, all support Belany's theory that infection is caused by the bed bug. There was also an increase in kala-azar, which caused 162 deaths (0·69 per 1000), as compared with 97 deaths in 1919; but 48 of these were imported cases. More than 25 per cent. of the deaths (misprinted "cases" on p. 35) occurred in Wards 1, 9, and 22 (Shampuker, Mocheepara, and Bhowanipur).

As to sanitary work generally, many important improvements were carried out in regard to drainage, insanitary buildings, and supervision of food supplies; unfortunately no further progress was made during the year in connexion with the scheme for a dairy-farm and city dairy prepared by Lieut.-Colonel J. Matson. A vigorous vaccination campaign was carried out, the total number (primary and revaccinations) performed amounting to 222,092; in 23,281 primary, with a success ratio of 99·2 in four-point insertions, and 98·8 in two-point insertions. Bacteriological examination of the Hooghly water showed a total count varying from 11,000 to 1,170,000 per c.cm., lactose fermenters being present in 0·1 c.cm. in 67 per cent. of the samples; after settling and filtration the total count varied from 5 to 68 per c.cm., and lactose fermenters were always absent in 10 c.cm.

This most valuable report contains much other matter of interest, and is illustrated by numerous diagrams, and a useful plan of the city showing ward boundaries. According to Whitaker, the population of Calcutta (in 1921) was 1,263,292; it is therefore the largest city in our Empire, after London. The responsibility of the health administration is very great, and the difficulties it has to contend with enormous. This report contains ample evidence of the skill, energy, and perseverance of the medical officer, and his staff, in the face of difficulties which can only be fully appreciated by those who are familiar with the climate, and the people, and the conditions of life that produce an infantile mortality ratio of 300 to 600 per 1000 births.

THE ENGLISH COLONY IN DAVOS.

DAVOS has in the recent winter regained something of its pre-war aspect. In the week ending March 2nd, 1923, out of a total 3146 visitors (106 whereof were tourists) 306 were of British and 59 of American nationality. Swiss were 1292, Dutch 362, Germans and Austrians 297, and French 209. During the whole winter season, since Oct. 1st, 1922, 980 British and 130 American visitors were present. The English Sanatorium in the Hotel Frei, to which Dr. A. F. Bill and Dr. Florian Buol are visiting physicians, had 26 inmates on March 2nd, not including Mr. C. Healy, secretary, and Nurse Margaret Pestalozzi.

POST-NATAL CYANOSIS.

To the Editor of THE LANCET.

SIR,—In some cases of cyanosis occurring in infants at an interval after birth a simple but efficacious way of overcoming an alarming condition is to keep the child in a position of semi-inversion by tilting its cot at an angle of 35° to 40°. In the three instances that I have encountered each patient seemed to be almost in extremis, but when this posture was adopted was quickly relieved, and each made a complete recovery.—I am, Sir, yours faithfully,

Birmingham, March 7th. FRANK PARRY, L.R.C.P. Irel.

THE NATION'S YOUTH AND THE DRINK BILL.

IN the *Times* of March 13th appears, over the signatures of Lord Dawson, Sir Thomas Barlow, Sir Thomas Horder, and Sir George H. Makins, a letter calling for the support of all who are interested in the physical and moral welfare of young people for the Teachers' Bill amending the law relating to the sale of intoxicating liquor to adolescents. To this measure, which Lady Astor introduced in Parliament on March 9th, we referred in our last week's issue (p. 500). We are glad to note such evidence of medical support for the Bill, which, to quote Lord Dawson and his colleagues, "is a matter quite apart from the principle of general prohibition."

SCHOOL ABSENCES OF BOYS AND GIRLS.

A COMPARISON of absences from school on account of sickness has been carried out by Mr. E. D. Collins, assistant statistician to the United States Public Health Service, who found that in practically all age-groups the girls were absent from school from sickness more than the boys. Taking all ages together the rate for girls was 9 per cent. greater than for boys. Taking absences from other causes than sickness, boys showed 18 per cent. more absences than girls. Comparing age curves of absence from sickness, it appears that the two curves are similar—high at 6–7 years and declining as age increases. In absence from other causes than sickness the curve decreased up to 10 or 11 years, and then increased with age.

THE ORDER OF ST. JOHN: SPA TREATMENT AT LLANDRINDOD WELLS.

WE have received from the Order of the Hospitallers of St. John of Jerusalem (Priory for Wales) a booklet descriptive of the spa treatment at Llandrindod Wells, instituted by the Order. Here disabled ex-Service men under the Ministry of Pensions, and civilians also, can obtain good accommodation and medical attendance at a modest figure.

The institution has been established for the accommodation and treatment of those suffering from the effects of rheumatic and gouty conditions, neuritis, colitis, obesity, eczema and skin complaints, liver, and other trouble due to residence in tropical climates, dyspepsia, debility, stomach complaints, &c. No infectious or incurable cases are accepted. Applications for admission (which are considered in rotation) should be addressed to the Secretary, with a letter of recommendation from a responsible person or approved institution, testifying to the applicant's inability to pay ordinary fees. The weekly tariff, including board, accommodation, treatment, waters, and medical attendance (one visit per week) is 3½ guineas. The average length of stay is four weeks, the Order reserving the right to terminate treatment at any time; the principal object of the establishment is to provide not holiday accommodation, but definite spa treatment. All communications should be addressed to Mr. George R. Baillie, Spa Treatment Establishment, Llandrindod Wells, Mid-Wales.

CARE OF MATERNITY IN SPAIN.

AN Act which has just been passed gives the Spanish Government power to proceed with the ratification of the "Maternity Convention" adopted by the First International Labour Conference held at Washington in 1919. Under the terms of this Convention it is provided that a woman in any public or private industrial and commercial undertaking shall not be permitted to work during the six weeks following confinement and shall have the right to leave her work six weeks beforehand on production of a medical certificate. During this time she shall be paid benefits sufficient for the full and healthy maintenance of herself and her child, provided either out of public funds or by means of a system of insurance, and, as an additional benefit, shall be entitled to free medical attendance. She shall also, if nursing her child, be allowed half an hour twice a day during her working hours for this purpose. The same Act authorises the Spanish Government to institute, as a means of applying these provisions, a compulsory maternity insurance system, the scheme of which shall be drawn up by the Ministry of Labour after consultation with the Institute of National Welfare.

DETECTION OF UNERUPTED HUTCHINSONIAN TEETH BY X RAYS.

THE presence of Hutchinsonian teeth in congenital syphilis has long been recognised as a valuable diagnostic sign, although their absence by no means precludes the diagnosis of syphilis. It frequently happens that when the teeth are affected so many other signs are present that the diagnosis is beyond doubt, but, when the diagnosis is not easy to make, it becomes important to discover every sign which may point to congenital syphilis. The upper central incisors, which are the typical teeth affected, do not erupt until about the age of 7, so that ordinary clinical examination cannot give information on this point before that age. J. H. Stokes and Boyd Gardner, in an interesting note in the *Journal of the American Medical Association* for Jan. 6th, 1923, point out that the shape of these teeth can be determined by a radiograph before their eruption. The upper incisors begin to calcify during the first year of life and the crowns are complete at about three and a half years: thus, from the age of 3 sufficient of the crown has been formed to demonstrate the peculiar shape of these teeth in congenital syphilis. It must be remembered that only a minority of children with congenital syphilis present Hutchinsonian teeth, but on the other hand there are cases in which the dental stigma may be chief, or, indeed, the only distinct sign present. Radiography is now generally available, while an intra-oral film is not difficult to take, even in a child, so that this method of ascertaining the shape of the unerupted incisors should prove useful in doubtful cases.

PUBLIC HEALTH IN HONG-KONG.

IN a report for 1921, prepared by the Colonial Secretary, Mr. A. G. M. Fletcher, it is stated that, according to the census taken in April, the civil population was 625,166, as compared with 561,026 in 1911. The non-Chinese community numbered about 14,000. The birth-rate is put at 5·68 per 1000 among the Chinese (though this figure is wholly misleading, as it is impossible to register more than a portion of the births) and 25·88 per 1000 among the non-Chinese. The death-rate for the year was 20·29 per 1000 among the Chinese and 18·08 among the non-Chinese. There were 332 deaths from malaria, 130 from plague, and 162 from small-pox. Deaths from respiratory diseases other than pulmonary tuberculosis numbered 3832. Pulmonary tuberculosis claimed 1318 Chinese and 25 non-Chinese victims, whilst other forms of tuberculosis accounted for an additional 576 deaths. Beri-beri was responsible for 526 deaths, as against 361 in 1920 and 555 in 1919. In the Civil Hospital, which contains 170 beds, 4815 in-patients and 27,322 out-patients were treated during 1921. Victoria Hospital at the Peak contains 41 beds, and 213 patients were treated there. At Kennedy Town Infectious Diseases Hospital 70 cases were treated. At the Tung Wa Hospital (for Chinese only) there are 330 beds, and 7211 patients were accommodated during 1921. Four district plague hospitals are maintained by the Chinese in various parts of the colony. The Kwong Wa Hospital for Chinese, in the Kowloon peninsula was opened in 1911; the patients treated there during 1921 numbered 4486.

Goulstonian Lectures

[ABRIDGED]

ON THE

NATURE OF ARTERIO-SCLEROSIS.

Delivered before the Royal College of Physicians of London on March 6th, 8th, and 13th, respectively,

By GEOFFREY EVANS, M.D. Camb.,
F.R.C.P. Lond.,
ASSISTANT DIRECTOR, MEDICAL UNIT, AND ASSISTANT PHYSICIAN, ST. BARTHOLOMEW'S HOSPITAL.

Lecture I.

In leaving £200 for the maintenance of these annual lectures, Dr. Theodore Goulston directed that a dead body should, if possible, be procured and two or more diseases treated of. Arterio-sclerosis, as it happens, fulfils both conditions, since it is largely based on post-mortem study and includes two or more diseases. It is too often depicted as a permanent pathological change, the final result of a process of arterial decay. There is a mark of finality about these structural changes in vessel walls due to the accidental circumstance of their being chiefly studied after death, due also in part to the degenerative changes being more obvious than the proliferative, and in part to arterio-sclerosis being more common in the old than in the young; hence the discovery of these changes during life tends to be accepted as evidence of wear and tear significant of an irrevocable step towards the grave. It is my purpose to bring forward some facts that will give this slow process of arterial "decay" some vitality and life, for I think it can be shown to be a process of disease with an onset that as yet escapes clinical recognition, and a course in which arrest or recovery are more common than death.

Definition of Arterio-sclerosis.

The problem of arterio-sclerosis is faced at once by the difficulty of its definition. Osler defined it as a condition of thickening of the arterial coats, with degeneration diffuse or circumscribed. This definition states the two essential criteria of arterio-sclerosis and excludes such lesions as peri-arteritis nodosa, thrombo-angeitis obliterans, intimal thickening of ligatured vessels, and vascular lesions near foci of suppuration, since fatty degeneration is characteristically absent in them. The definition being based on a description of anatomical lesions alone is incomplete and therefore too inclusive; it makes no reference to the nature of the underlying process nor to the problem of causation. In their definition of arterio-sclerosis both Thorel and Marchand take into account the underlying process, and in addition to emphasising the importance of intimal thickening, refer to degenerative changes, inflammatory and productive processes. Further arterial lesions whose causation is known do not belong to arterio-sclerosis but are placed under their specific title. Thus syphilitic endarteritis is excluded, though syphilis has to be taken into account in the ætiology of arterio-sclerosis when the anatomical lesion is that of arterio-sclerosis and the possibility of its being syphilitic is suspected but not assured.

The Problem of Arterio-sclerosis and its Classification.

As Sir Clifford Allbutt has often insisted arterio-sclerosis is not a disease. The word should only be used in a pathological sense to define a lesion which is common to many diseases. There are three distinct aspects of the problem—namely, the description of the vascular lesion, the relative importance in the production of this lesion of various pathological and physiological processes, and lastly, its causation. There is a fair measure of agreement as to the description of the lesion; there is, however, no accepted opinion as to the nature of the processes concerned in its production, and its causation is largely hypothetical.

Classification.—Arterio-sclerosis is too large a subject to be considered as a whole in detail. It is conveniently divided into four main types based on anatomical changes—namely, nodular, diffuse hyperplastic, senile, and Mönckeberg's sclerosis. This is Councilman's classification with the addition of Mönckeberg's sclerosis. These are the distinct forms: there are others which are classified according to the type to which they most closely conform. For the present I am chiefly concerned with the type of arterio-sclerosis termed diffuse hyperplastic sclerosis; its relation to the other three types of arterio-sclerosis will be considered in the third lecture.

Diffuse Hyperplastic Sclerosis.

This type of arterio-sclerosis was originally described by Gull and Sutton under the name of arterio-capillary fibrosis, and its histology was the subject of controversy between Gull and Johnson. It has been described in some detail by Jores, Aschoff, and Gaskell. It is found in children with renal disease, and in adults with chronic nephritis (chronic parenchymatous nephritis or chronic diffuse nephritis) and with true chronic interstitial nephritis, also, as will be discussed later, in association with left ventricle hypertrophy and raised blood pressure; and lastly, in certain cases as an incident when death has resulted from some other not related cause.

Histology of Diffuse Hyperplastic Sclerosis.

The essential lesion is a thickening of the intima in the smaller and smallest arteries. The initial lesion in the arterioles is a swelling and proliferation of the endothelial cells. The second stage of the process is the fatty degeneration of these cells. The final stage is their complete degeneration and blocking of the lumen of the vessel. The initial lesion in the *parent* vessels of these terminal arterioles is also proliferation of the endothelium. The next stage, or one that occurs simultaneously, is an increase in the intercellular substance, formation of fibrillar tissue and elastic fibres. The increase of elastic fibres appears as a fine network in the inner layer of the intima, and as a hyperplasia (Jores) of the internal elastic lamina. Characteristically fatty degeneration does not occur in these vessels; it begins abruptly in the terminal artery at its origin from the parent vessel. These changes lead to a marked degree of narrowing of the lumen. The vessels from which these so-called parent arteries are given off are similarly affected. No lesion that could be described as typical of diffuse hyperplastic sclerosis has been identified in the larger vessels. The lesion of diffuse hyperplastic sclerosis is in fact only to be identified in the smaller vessels. Its distribution in the circumference of a vessel is fairly uniform, as is its distribution in the length of a vessel. Only a small proportion of vessels in an organ may be affected. In marked cases in which there has been a persistently raised blood pressure during life there is thickening of the media. Occasionally there seems to be some increase in the adventitia in the renal and splenic vessels. Its distribution in the several organs appears to be fairly constant, the kidney being the organ most frequently affected, the spleen being the best indication of the degree and extent of the lesion in the body as a whole. More or less in the frequency of its incidence the brain, pancreas, liver, suprarenal, stomach, and intestines, come next in order. The heart, skeletal muscles, and lung are rarely affected, and I have no specimen of the lesion in these organs; other organs in the body have not been examined in sufficient numbers to place in this table of incidence.

The thickened intima of the parent vessels is formed of cells lying in the hyaline matrix, which is permeated by fine elastic and connective-tissue fibrils. In its deeper layer are often several (two to six) laminæ of elastic tissue (Jores's hyperplastic layer). In recent lesions the lumen of the vessels is sometimes seen to be lined by successive layers of proliferated endothelial cells. The scattered cells beneath presumably have their origin from endothelial cells or result from proliferation of original intimal cells.

Endothelial cells are known to form connective tissue (Baumgarten, Spilsbury), and the origin of the connective-tissue fibres in the inner layer of the thickened intima is from endothelial cells or from the original connective-tissue cells in this layer. Elastic-tissue fibres are laid down by cells of the connective-tissue type (Jores), and the elastic fibres in the thickened intima result from the activity of such cells, or as Jores has suggested, as a process of growth into the intima of the elastic fibres in the media. Jores has suggested that the laminæ and elastic-tissue that form the outer part of the thickened intima are formed by a process of swelling and splitting of the internal elastic lamina. The possibility of elastic fibres arising in this manner is contrary to the accepted canons of biology (Virchow), since elastic-tissue fibres have no nuclei and though living are inert. In fact, the formation of the laminæ of elastic tissue in the hyperplastic layer is perhaps more nearly analogous to the formation of banded precipitates in gelatin solutions, a physico-chemical reaction known as the Liesegang phenomenon, in which the process of adsorption is closely concerned. Sections were shown which pointed to the formation of elastic fibres by endothelial cells, a method of formation which has previously been suggested by Heubner and others. The nature of hyaline was discussed, and it was held to be equivocal evidence of degeneration. The fact that the intimal thickening in the parent arteries, which is largely due to the formation of hyaline, does not progress to fatty degeneration, as also the absence of any sign of degeneration in the cells in this layer, is evidence against the view that hyaline is produced by a process of degeneration in diffuse hyperplastic sclerosis. It may indeed be formed by a process of secretion by endothelial cells (Lorrain Smith), in which case the process concerned in its production is one of inflammation.

The main feature of diffuse hyperplastic sclerosis is a thickening of the intima, accompanied sometimes by hypertrophy of the media. The intimal changes are the essential lesion. Activity of the endothelial cells is largely responsible for the intimal thickening. In this thickening the process of degeneration plays a secondary part; it is only certainly present in the terminal arterioles of the kidney and the smallest vessels of the other organs. The characteristic feature of the lesion is an intense tissue activity which is the antithesis of a process of decay.

LECTURE II.

The nature of the process concerned in the development of the lesion is the next aspect of its pathology to be considered. From a theoretical standpoint there are four possible processes involved—namely, involution, growth, degeneration, and inflammation.

INVOLUTION.

Thoma's view of arterio-sclerosis was based on the changes observed in the aorta on the interruption of the placental circulation at birth. He observed a thickening of the intima between the origin of the ductus arteriosus and the origin of the umbilical arteries due to cellular proliferation and the formation of connective tissue in the subendothelial layer. This change was compared to the intimal thickening that occurs in arteries that have been naturally or artificially occluded. Thoma ascribed these changes to slowing of the blood-stream and maintained that the same process was concerned in the production of arterio-sclerosis. In the case of nodular sclerosis he postulated a primary weakening of the media with consequent bulging of the vessel wall, as a result of slowing of the blood-stream and thickening of the intima. In the case of diffuse arterio-sclerosis, he postulated a reduction in size of capillary fields as a result of disease with a consequent reduction in the amount of blood flowing through the arteries supplying the reduced area. In its original form this theory of arterio-sclerosis is no longer tenable, but in so far as it includes the idea of a replacement fibrosis the theory holds good.

GROWTH.

Jores finds the basic explanation of the anatomical lesions in arterio-sclerosis in the intimal changes that occur in the aorta in the natural process of growth. He has distinguished the intimal changes in arterio-sclerosis by the proliferation and splitting of the internal elastic lamina from endarteritis in which the formation of a connective tissue layer in the intima is the prominent feature. He regards the process as one of hyperplasia due to an increased functional demand on the vessel wall. His important contribution to the subject is the observation that the initial lesion is in the intima and that degeneration is a subsequent event. The distinction between hyperplastic and fibrotic layers is, however, difficult to maintain, and his theory as to the manner of formation of elastic tissue seems to be wrong in principle. The chief objection to Jores's theory is the difficulty of explaining either the form of the lesion or its distribution in terms of an increased functional demand on the vessel wall.

DEGENERATION.

Marchand is chosen to represent this theory because he has so far made it his own as to suggest the word "athero-sclerosis" in place of arterio-sclerosis. The theory turns on the question of priority of degenerative or proliferative change in the vessel wall in arterio-sclerosis. If the presence of fat is accepted as the criterion of degeneration the matter is simple. I have shown that the initial lesion in diffuse hyperplastic sclerosis is a proliferation of endothelial cells; Klotz has shown that proliferative changes are either initial or coincident with degenerative changes in nodular sclerosis; Klotz also has shown that degenerative changes in the media are initial in senile arterio-sclerosis. There is no question that degenerative changes are an essential feature of arterio-sclerosis taken as a whole.

INFLAMMATION.

Virchow attributed arterio-sclerosis to an inflammation of the vessel wall and compared it directly to endocarditis. There are two important objections to this theory. In the first place Jores made a sharp distinction between the histological lesion of arterio-sclerosis and that of frank endarteritis; in the second place the ordinary signs of inflammation are not apparent in arterio-sclerosis. With regard to the first objection it is maintained that there is no hard-and-fast distinction between arterio-sclerotic and inflammatory lesions; and with regard to the second objection, the fact that vascular walls are largely avascular tissues may be a determining factor. In fact, inflammation in an artery is comparable to inflammation in the cornea, and since endothelial proliferation occurs in arterio-sclerosis this lesion comes to be more obviously inflammatory from a purely anatomical point of view than keratitis. Changes that occur in articular cartilage in osteo-arthritis were compared with the lesion of arterio-sclerosis, and Timbrell Fisher's views on the importance of the blood-supply in determining the character of the tissue response to injury suggest a reason for the relative degree of proliferative and degenerative change in arterio-sclerosis.

The key to the problem turns on the fact of endothelial proliferation in arterio-sclerosis. Vascular endothelium pays a very active part in inflammation (Adami). In chronic inflammation the endothelial cells of capillaries and arterioles swell and proliferate to such an extent as to lead ultimately to occlusion of the vessels. Anatomical changes must be interpreted in terms of the function of the tissues they concern. Thus an increase in the number of the muscle cells of the media is evidence perhaps of the existence of a mechanical factor, but an increase in the number of endothelial cells of the intima is evidence of the existence of a toxic factor. Thus the actual form of the lesion in diffuse hyperplastic sclerosis taken in conjunction with the function of endothelial cells is evidence that the process of inflammation is responsible for the production of the lesion.

The theory of productive fibrosis was analysed in terms of Jores and Thoma's theories, and finally reference was made to the possibility of the autochthonous development of arterio-sclerosis. The view was maintained that the simple process of inflammation is sufficient explanation of the production of the lesion in diffuse hyperplastic sclerosis.

LECTURE III.

The causation of diffuse hyperplastic sclerosis and its relation to other forms of arterio-sclerosis remain for consideration. Since diffuse hyperplastic sclerosis has not been produced experimentally, only clinical evidence on causation is available, and before this can be discussed the clinical diagnosis of diffuse hyperplastic sclerosis needs to be established. Its diagnosis is necessarily a matter of inference, since tissue for microscopical examination is rarely available during life, and the vascular changes in the fundus oculi are not yet so closely correlated with the histological lesions as to allow of a final diagnosis by the ophthalmoscope. The clinical picture can be established, however, on the basis of the naked-eye post-mortem indications of the presence of the lesion.

NAKED-EYE POST-MORTEM EVIDENCE OF DIFFUSE HYPERPLASTIC SCLEROSIS.

The presence of diffuse hyperplastic sclerosis, apart from histological examination of tissues, is indicated by the appearance of thickening of the smaller arteries, especially of the kidneys and spleen, and the vessels are seen to protrude like little quills on the cut surface of these organs. When there has been a raised blood pressure during life the walls of the larger arteries, such as the splenic and iliac arteries, are obviously thickened, and the hypertrophied media shows as small transverse ridges on the inner surface of the vessel wall.

Cardiac hypertrophy, especially involving the left ventricle when not due to disease of the heart and lungs, is termed "idiopathic hypertrophy" for the present purpose, and it is the most important evidence, though not proof, of diffuse hyperplastic sclerosis. Its significance in this respect has been tested by two lines of inquiry. In the first place, an analysis of 20 consecutive years of medical post-mortem records of St. Bartholomew's Hospital showed that idiopathic cardiac hypertrophy of more than 15 oz. weight was significant of cardio-vasculo-renal disease. In the second place, I have found diffuse hyperplastic sclerosis in all cases with idiopathic hypertrophy whose tissues I have examined microscopically. The hypertrophy of the heart and of the media of the arteries can be regarded as a physiological expression of increased activity during life. The only essentially pathological sign of diffuse hyperplastic sclerosis is renal sclerosis in one of its several forms. In short, the essential post-mortem picture of diffuse hyperplastic sclerosis is limited to the cardio-vasculo-renal system; it consists of left ventricle hypertrophy, the appearance of medial thickening, and renal sclerosis.

CLINICAL PICTURE OF DIFFUSE HYPERPLASTIC SCLEROSIS.

The clinical diagnosis of diffuse hyperplastic sclerosis is based on the foregoing post mortem-evidence of its presence. A definite though not direct relation is present between idiopathic cardiac hypertrophy and raised blood pressure. The clinical diagnosis of the former may be difficult, since disease of the myocardium cannot always be excluded. A record of the blood pressure is very easily taken, and is important confirmatory evidence of idiopathic cardiac hypertrophy. For reasons given a systolic pressure of 180 mm. Hg is regarded as having a pathological significance provided the reading is taken under good conditions. In short, my view is that the clinical signs of diffuse hyperplastic sclerosis are idiopathic cardiac hypertrophy (standard being 15 oz. weight post mortem) and a raised systolic pressure (180 mm. Hg). The various diseases in which these two signs are present will now be considered.

1. *Hyperpiesia.*

Sir Clifford Allbutt introduced this term to define a group of cases characterised by a persistently raised blood pressure with cardiac hypertrophy but without kidney disease. Cases of hyperpiesia may respond to treatment and recover, or alternatively they may pursue their own course and terminate in death. In the latter event the disease preserves its identity as a morbid series and does not pass through or into Bright's disease. In view of the relation of cardiac hypertrophy and raised blood pressure to diffuse hyperplastic sclerosis, and since these are the cardinal signs of hyperpiesia, I suggest that the clinical expression of diffuse hyperplastic sclerosis is hyperpiesia. The connexion between hyperpiesia and arterio-sclerosis is so close that it is often regarded as one of cause and effect. The older view, that the vascular lesion is the cause of hypertension, is no longer tenable. The view that hypertension is the cause of arterio-sclerosis is expressed by Sir Clifford Allbutt in his distinction of a hyperpietic form of arterio-sclerosis. Reasons for and against this view were discussed, and the conclusion was reached that hyperpiesia and diffuse hyperplastic sclerosis are the simultaneous results of the action of a common cause.

2. *Renal Sclerosis.*

There is some degree of renal sclerosis in all cases of diffuse hyperplastic sclerosis, and there is some vascular lesion in all cases of renal sclerosis. Renal sclerosis is divisible into two main groups according to the distribution of the lesion in the organ.

Group (1), Chronic Nephritis.—The essential lesion is a glomerulitis, and both it and the new formation of fibrous connective tissue is distributed widely throughout the kidney. Taken as a whole and in their more chronic forms, these kidneys tend to be associated with diffuse hyperplastic sclerosis and cardiac hypertrophy. The renal lesion is without doubt inflammatory and is further evidence in favour of the inflammatory nature of the vascular lesion.

Group (2) includes all kidneys in which the lesion is partial, being limited to wedge-shaped areas of fibrosis containing damaged renal parenchyma and more or less small-cell infiltration. The intervening tissue is relatively normal, and the parenchyma may be hypertrophied.

Subgroup (a).—True chronic interstitial nephritis. In these kidneys there is histological evidence of active inflammation. The most marked cases of diffuse hyperplastic sclerosis are often found in this subgroup, and they are associated with the highest blood pressures. These cases with their definitely inflammatory renal lesion are further evidence of the inflammatory nature of diffuse hyperplastic sclerosis. It is maintained that diffuse hyperplastic sclerosis shares a common ætiology with chronic nephritis and chronic interstitial nephritis.

Subgroup (b).—True arterio-sclerotic kidneys. These are subdivided into two types according to whether the accompanying vascular lesion is of the type of diffuse hyperplastic sclerosis or senile arterio-sclerosis. Histologically there is no evidence of glomerulitis in kidneys of this subgroup. The renal lesion is only evidenced in a trace of albumin in the urine, the urine being of good colour and normal specific gravity. Of the two types included in this subgroup, the one in which there is diffuse hyperplastic sclerosis is the more important, since it is associated with raised blood pressure and cardiac hypertrophy and is in fact clinically hyperpiesia.

The basic proposition that I have attempted to present in this outline of the relation of hyperpiesia and renal sclerosis to diffuse hyperplastic sclerosis is, that the causation of the vascular lesion is the same as that of hyperpiesia and renal sclerosis. The ætiology of these conditions, so far as known at present, is due to the action of bacterial toxins, and both the character of the vascular lesion in diffuse hyperplastic sclerosis and the distribution of the lesion in the vascular tree is compatible with the view that it also is caused by a circulating toxin.

Relation of Other Forms of Arterio-sclerosis to Diffuse Hyperplastic Sclerosis.

1. *Nodular Sclerosis.*—This lesion is like diffuse hyperplastic sclerosis in that the initial change is in the intima and is a thickening of this coat due to proliferation of superficial cells, which Klotz regards as of endothelial or connective-tissue origin. The thickened intima is permeated by elastic fibrils at a later stage; fatty degeneration occurs subsequently, perhaps as a result of deficient oxygen supply. Klotz and Manning have made a minute study of the histology of the fatty streaks and spots that are chiefly found in the aorta and in the main vessels arising from it. These lesions may develop into nodular sclerosis or may heal. The authors go on to say, "there is every indication that the production of tissue in the intima is the result of a direct irritation of that tissue by the presence of infection or toxins or of the stimulation by the products of a primary degeneration in that layer." There is also reason to believe that the intimal thickening is in some cases compensatory to a primary affection of the underlying media.

2. *Senile Arterio-sclerosis* is primarily a medial degeneration beginning with fatty degeneration and atrophy of the muscle fibres and affecting both larger and smaller vessels (Klotz). These changes are followed by replacement fibrosis and deposit of lime salts in the media. Thickening of the intima is generally an accompaniment of senile arterio-sclerosis, either as a diffuse affection or focal (nodular sclerosis), or more commonly both combined. Age is more definitely a factor in its causation than in diffuse hyperplastic sclerosis; it differs also in its clinical expression, being unaccompanied by hypertension and cardiac hypertrophy. Senile arterio-sclerosis is as diffuse in its distribution as diffuse hyperplastic sclerosis, but it differs from it both in respect of the site and the character of the initial lesion. There is both clinical and experimental evidence that mechanical and toxic factors are responsible for its production.

3. *Mönckeberg's Sclerosis* is often included under the title of senile arterio-sclerosis; the lesion begins in the media as a fatty degeneration followed by massive calcification. In a sense it is more senile than senile arterio-sclerosis since the intima often fails to proliferate, as though too weak to respond either to the factors responsible for the medial degeneration or to the medial degeneration itself. It is not age, however, that has weakened the vessel wall but disease; thus of the 12 pure cases described in Mönckeberg's original paper four died of cancer, four of phthisis, one of heart disease, and three of cachexia due to chronic infection. I think it is here that diabetes mellitus sometimes finds its place in the ætiology of arterio-sclerosis.

Summary.

The study of the pathology of arterio-sclerosis has impressed me with the vivid picture of reaction in tissues to insult, response to injury, and repair of damage done. Great students of pathology such as Virchow interpreted the lesion in terms of inflammation, Thoma in terms of involution, and Jores in terms of growth. These men, at least, have failed to grasp the cloven hoof of arterial decadence and decay. It is asking too much to expect a restitutio ad integrum in arterio-sclerosis, and as in tuberculosis of the lung we may be content with a lesion that heals by calcification and fibrosis. The prospect of recovery in vascular tissue is indeed better than in parenchyma of the lung since new vessels are formed with ease and rapidity to take the place of those destroyed by disease. Vessels that cannot be replaced by others achieve considerable success in resisting the process of disease, and one of the best examples of this power of resistance is the rarity of aneurysm of the aorta as a result of arterio-sclerosis.

Since the problem of arterio-sclerosis is contained in its definition, I will end by stating the problem as I have tried to outline it:—

Arterio-sclerosis is a lesion characterised by a pathological thickening of arterial coats, particularly of the intima; inflammatory reaction is of first importance; degenerative changes are an essential part of the picture; hyperplastic and involutionary processes play a part; no unit factor is responsible for its causation. Its development in its extent and form depends on a balance between the action of toxic agents and the power of resistance of the vessel wall to their attack.

A Lecture

ON THE TREATMENT OF
EPITHELIAL TUMOURS OF THE URINARY BLADDER,

BASED ON A CONSIDERATION OF 162 CASES PERSONALLY OBSERVED AND TREATED.

Delivered at the Mayo Clinic, Rochester, Minnesota, U.S.A.,

By FRANK KIDD, M.A., M.Ch. Camb.,
F.R.C.S. Eng.,

LATE SURGEON TO THE LONDON HOSPITAL, ENGLAND; [redacted] OF THE INTERNATIONAL SOCIETY OF UROLOGY; [redacted] DE L'ASSOCIATION FRANÇAISE D'UROLOGIE.

(*Continued from p. 527.*)

Group 3.—Malignant Papilloma or Early Carcinoma.

In this group were 26 cases of malignant papillomata or very early carcinomata, considered as malignant either on clinical appearance or on their resistance to diathermy treatment, or as a result of previous operations by other surgeons, microscopic sections having been made and investigated. It is a very difficult question to decide, when we are faced with a man getting on in years who has only exhibited hæmaturia for a short time and in whom a single large somewhat bald papilloma is seen with a broad and rather sessile pedicle and very large veins running to the pedicle, as to whether to try the effects of diathermy before proceeding to subtotal cystectomy. Scientifically it is the right thing, and most to the benefit of the patient, to try diathermy first; in several of my cases, especially since I have had my new machine, I have been able to destroy quickly and successfully what appeared to me to be large and malignant papillomata. Yet in practice things work out differently. After three or four unsuccessful diathermy treatments, when you proceed to tell your patient that facts are against you and that clearly his papilloma is malignant, will not react to diathermy and needs open operation, he may lose faith and either go off to another surgeon or give up treatment altogether. Personally I find it one of the most difficult questions to decide as to what to do in these cases. As a result of experience I am now inclined to advise partial cystectomy in doubtful and difficult cases rather than to run the risk of sickening my patients with unsuccessful diathermy.

Of these 26 cases 12 proved resistant to diathermy. I submitted four to partial cystectomy, two of whom are alive and well up to 1922, seven years since their operations. One remained well for three years and then appeared to develop a fresh carcinoma and died of it. One was submitted to partial cystectomy and died after the operation. Three were operated on by other surgeons and all relapsed very quickly and died. Five refused further treatment; one of these was lost sight of, the other four died within less than two years.

Fourteen of these tumours were observed to have been completely destroyed by the treatment. Of these 14 cases nine were heard of as late as 1922 and are known to have been cured of their trouble, some as long as six or seven years from their treatment. The others were followed up for some time and remained free from recurrence, but cannot be traced up to 1922. An old man of 75 with a failing heart and enlarged prostate cystoscoped in 1914 was too unstable as regarded his heart condition to be submitted to prostatectomy. In 1914 I destroyed two early malignant papillomata. He had no trouble until he developed hæmaturia in 1916, and I then destroyed a single early malignant papilloma. He went on quite comfortably and well until 1920, when I cystoscoped him again. He then had what appeared to be an entirely fresh ulcerating carcinoma of the base of the bladder, for which no treatment could be carried out, and which caused his death in 1921 at the age of 82. By means of diathermy this man, on whom a major surgical attack was completely out of the question, was given six years of comfortable and untroubled life. Another patient seen in 1915 had a large sessile malignant papilloma above the right ureter which resisted diathermy. I performed subtotal cystectomy and reimplantation of the right ureter in 1915. As he had no recurrence, in 1919 I removed his prostate which was giving him trouble. He is alive and well at the present day, seven years later, and leading a valuable business life.

The attitude of the general surgeon and operating practitioner to this line of work is well illustrated by the following cases. It is difficult to understand the attitude of a surgeon who knows that diathermy can be used through the cystoscope and yet who prefers to open the bladder himself rather than send the case to a specialist. One patient had an open operation by another surgeon in 1917. In 1920 he had recurrence. A provincial surgeon administered anæsthesia for purposes of cystoscopy. As the patient was about to " go under " the surgeon actually asked the patient whether he would prefer to let him deal at once with a recurrence if found by open operation or whether he would wait and come up and see me for diathermy. The patient very naturally said " Get on with it." The result of the second operation was recurrence within a year. So far I have seen the patient three times and on each occasion have been able to destroy a small recurrence with diathermy. He is now beginning to wonder why he needed the open operation. Another patient, aged 69 years, developed hæmaturia. His doctor and a specialist in a provincial town purchased a cystoscope, and, as luck would have it, saw a papilloma. Between them they cut down and snipped it out. Within three months recurrence took place and they brought him up to me. Every three months I cystoscope him and destroy small recurrences on the bladder abdominal scar. This patient is also beginning to wonder why he was submitted to open operation. One patient, the wife of a doctor, had bled for six years before being sent up for cystoscopy. I was even then able to cure her by subtotal cystectomy.

One patient, a woman, attended twice for diathermy. After the first treatment I could see that half her growth, which was then of moderate size and single, had already been destroyed, but she did not attend again. I include the reply of her doctor to my follow-up letter as it illustrates sufficiently the difficulties we are up against.

Re Mrs. . . . . . .

SIR,—Sent you by the gynæcologist, she had previously been operated on. She soon grew tired of the pretentious attempts to sweep back the sea of malignant papilloma with the besom of an electrical cautery. I thereon sent her to see an operative bladder surgeon who removed from her bladder three such growths with a total superficial area of 5 square inches. Unfortunately the suprapubic wound became infected with the cancer juices and recurrence in the operative site occurred within a period of two months. She lingered for another five months, dying a painful death from cachexia, bowel infection, and skin cancer (epithelioma or rather endothelioma). I hope you have been more fortunate in the diagnosis and treatment of the other cases that have fallen into your hands.

The old-fashioned idea of silver nitrate washes still holds the field. One of these patients had had the bladder washed out over 2000 times with silver nitrate on the advice of a surgeon, and another more than 400 times on the advice of another surgeon. Both these surgeons were well-known men and both knew what the correct diagnosis was. In contrast to this attitude may be quoted a case sent up by a practitioner within eight days of her first bleeding. Cystoscopy revealed the earliest little ulcerating carcinoma I have ever seen, with a clot adherent to it. I was able to destroy that completely at one sitting under an anæsthetic with diathermy.

Out of a total of 54 cases treated by diathermy through the cystoscope 28 cases are known to have been cured by the treatment. In 40 cases the tumours were completely destroyed, but the final results could not be followed up to 1922. Fourteen cases relapsed, only two of which were cases of simple papilloma, the others being cases of malignant papilloma on whom the effect of diathermy treatment was tried to test the nature of the growth and in the hope of avoiding an open operation. Of these four are still alive and well as the result of successful open operation. Diathermy applied through the cystoscope may therefore be expected to give at least 90 per cent. of cures in cases of simple papilloma of the bladder. Even in certain cases of early malignant papilloma and very early ulcerating carcinoma it may be worth a trial, provided the patient understands clearly what is being attempted and that he must be prepared for operation immediately it is seen that his tumour resists diathermy.

In a certain type of case met with in a youngish man with a short history multiple malignant papillomata are seen at the first cystoscopy. These may prove most refractory to diathermy, and even if partial cystectomy is performed, early recurrence may be expected. It is as if the whole bladder wall had acquired the habit of forming rapidly growing papillomata. In this type of case total cystectomy might be expected to be possible and even helpful. Unfortunately by the time things have come to this pass the patient may be so sick of interference that he prefers to let things slide and refuses the idea of total cystectomy with leakage of urine on to the skin or into the rectum. Nevertheless the future of total cystectomy lies chiefly in this type of case, and the work of Delfino referred to later may abolish the complication of urinary fistula. Other difficulties arise in dealing with these malignant cases. Some are elderly men and have enlarged prostates as well. This renders cystoscopy difficult and perhaps in these cases it would be better to do partial cystectomy and prostatectomy at the same time. Again, in cases of multiple papillomata round the internal meatus it is a very difficult matter to deal with them through an ordinary cystoscope. Mr. J. Swift Joly, of St. Peter's Hospital, London, has designed a very ingenious retrograde cystoscope[1] with a new type of spring lever which bends the electrode directly backwards. By this means it is possible to treat warts lying around the internal meatus. He has also designed a posterior urethroscope for dealing with this problem. Both are made by the Genito-Urinary Manufacturing Company and are worthy of notice. Nevertheless, in these difficult multiple cases I am now inclined not to waste time in cystoscopic diathermy, but to proceed at once to subtotal cystectomy combined, if need be, with open diathermy.

GROUP 4.—PARTIAL OR SUBTOTAL CYSTECTOMY.

This group contained 28 cases of partial or subtotal cystectomy with or without resection and reimplantation of one ureter. By partial or subtotal cystectomy I mean an operation carried out on the lines so admirably described by Bentley Squier, where the major portion of the bladder is freed from its vascular and fatty bed before it is opened, where the growth is removed from without with a large surrounding portion of bladder wall which usually includes the lower end of one ureter, and where this cut ureter is reimplanted into a bladder reconstructed from the portion of healthy bladder wall left behind. Although this is a severe operation, performed on old people suffering from a disease which promises an early and painful death apart from successful operation, yet increasing experience brings increasingly hopeful results. Twenty-two of these 28 patients survived the operation and went home healed up within a period that varied between three weeks and three months. Most of them were healed up and away within a month and most of them passed all their water naturally within 14 days of the operation. Secondary complications were rare. Two developed stones which had to be crushed a year or so later, and two developed a urinary sinus which took four months to heal; otherwise they did extremely well. The end-results were obtained in 24 patients, including the six fatal cases. Eleven are known to be alive and well in 1922, 1 11 years, 3 eight years, 2 seven years, 1 three years, 2 two years, and 2 more than one year since their operations. The 11 years' case was a small ulcerating carcinoma needing resection of one ureter, and two of the eight-year cases were of similar type. One went on for five years doing his work and apparently quite well, but he had a relapse of hæmaturia the very week I wrote to him in July, 1922. Another died six months later of perforated gastric ulcer. Four were traced for as long as two years and remained well but were then lost sight of. Five lived for periods of one up to five years and then developed recurrences and died of their disease. Eleven out of 28 are known to be cured and it is probable though not certain that 15 out of 28 were cured.

---

[1] Described and illustrated in THE LANCET, 1922, I., 1251.

Six of these patients died within a month of the operation. One, a stout elderly woman, had healed up and was passing water naturally and was about to get up, when she developed a severe lobar pneumonia due to the bacillus of Friedländer. After nine days she had a crisis and appeared to be doing well, when pneumonia appeared in the opposite lung and she could not survive the added burden. I doubt if this final result was directly due to the operation. One was an old man of 70, with a failing heart, and as blue as a jelly fish when I saw him. He had had the old-fashioned operation two years previously and had a recurrence. He knew the risk and wished to take it. The operation went off well enough under open ether and oxygen and in three weeks he was healing up satisfactorily, when he died of sudden heart failure, an accident to which he was liable at any time. One, a man of 67, died of sudden heart failure about a fortnight after his operation when he appeared to be healing up satisfactorily. One, a man aged 60, died of an ascending pyelitis and uræmia. One died from an intraperitoneal operation; the small gut became adherent to the scar on the top of the bladder, volvulus appeared on the third day, and led to death on the fifth day. Finally, death occurred in a comparatively young man, aged 42, who should have done well. It was war-time and I had an inexperienced house surgeon, who against my distinct orders told the dresser to wash out the bladder on the third day with an irrigator. The dresser placed the irrigator six feet above the bed, burst all the bladder stitches, and caused immediate death from shock. The after-treatment is of the highest importance in these cases. In 10 of the cases the after-care was completely in my own hands and only one of them died—namely, the woman who developed lobar pneumonia. I consider that the after-treatment is as important as regards the life of the patient as the technique of the operation itself.

It is difficult, then, to estimate the immediate mortality of partial cystectomy. Performed as it is in elderly people it presents risks inherent to the aged in the way of lung and heart complications, but it also presents a definite risk of ascending pyelitis and anuria due to cutting the ureter. I have entirely given up the intraperitoneal operation. I find the operation is more easily performed extraperitoneally, and opening the peritoneum definitely adds a risk of setting up intestinal obstruction. There is little risk of peritonitis, but the risk of obstruction from adhesion of small gut is a most definite one and occurred also in cases in Group 4.

OPERATION OF SUBTOTAL CYSTECTOMY.

The steps of the operation (which usually takes me $1\frac{1}{2}$ to $1\frac{3}{4}$ hours to perform, though I have done it in just over an hour) are as follows: I administer stovaine spinal anæsthesia so as to block the nerves and reduce shock ("anoci-association"), and to produce temporary paralysis of the bladder and lower abdomen, which prevents straining and diminishes the need for powerful and harmful retraction of the wound edges. Straight away I administer a little open ether and oxygen, so as to block the mental afferent impulses of fear and apprehension. In this way I have seldom met with shock, and the patients go off the table in excellent condition. Treated afterwards with sufficient morphia and rectal infusion of sodium bicarbonate and glucose, they have seldom given cause for anxiety as regards primary shock. The bladder is filled with eight ounces of 1 in 2000 oxycyanide of mercury solution. With the patient in the high Trendelenberg position an incision is made in the middle line from the pubes towards the umbilicus, but the peritoneum is not opened. The bladder is quickly cleared in front and laterally, and then great care is expended in stripping the peritoneum off the *superior* wall of the bladder. This yields to patient and careful handling. If the peritoneum should be torn it is at once stitched up again. The urachus and obliterated hypogastrics are defined, ligatured, and cut across so that the bladder can be pulled well forward and upwards out of the pelvis. The bladder is then cleared on one or both sides, according to the position of the growth, right down to the rectum, which is stripped bare. The vas is ligated and cut on the side of the growth, otherwise it gets in the way. The patient is quite unaware of this afterwards and I have observed that it has no effect whatever on the testicle. The ureter on the side of the growth is then exposed and cleared right down to the bladder. As this is done the *vascular fatty pedicle of the bladder* is defined as a narrow flat sheet of fatty tissue lying immediately outside the ureter. The vessels as they come off from the internal iliac artery and vein are ligated in turn—i.e., the superior vesical artery, usually a small vessel, and one or two large vessels corresponding to the inferior vesical artery, usually of large size (hypertrophy evoked by the presence of the growth). Below the arteries are found a number of large veins, an overgrowth of vascular tissue caused by the stimulus of the growth, a constant feature. It saves time and loss of blood to tie these before the bladder is opened. The ureter is cut across at its entrance to the bladder, its end cauterised to seal the lymphatics, and then laid aside in the wound. The ureter is usually dilated by pressure from the growth. *So far the bladder has not been opened*—an important point, as all this work has been done without any risk of implanting cells from the papilloma in the tissues. In clearing the bladder all fatty tissue is stripped towards the bladder and any enlarged glands along the external iliac vein and between the internal iliac veins are removed. The bladder is now opened with a long sharp bladder knife on its *superior wall* medially or laterally according to the position of the growth, and its contents caught in a soup ladle, a most useful implement. The practice of introducing swabs into the bladder to dry it out is a vicious one and leads to implantation. I deprecate the use of scissors in cutting any living tissue. Tissues cut cleanly with a knife heal more readily as they are not crushed. I prefer a knife to a Pacquelin cautery for the same reason. The position of the growth, already fairly accurately known from cystoscopy, is noted afresh and more exactly. According to this information I start several inches wide of the growth and cut boldly out a large piece of bladder wall, using a sharp knife and a set of volsella clamps for holding purposes. I prefer to remove too much rather than too little, and go as wide of the growth as it is possible to do on the lower side. On no account is an assistant allowed to finger the wound, and I endeavour not to touch the growth either with finger, instrument, or swab (a most important point). It should be looked upon as a most dangerous implanting agent and be respected as such. To this I attribute my lack of recurrence. Usually it does not take more than one to two minutes at longest to cut what I am going to cut out cleanly with a few sweeps of the knife, so that I take away the growth and bladder wall in one piece and clear it away at once into a receiver out of harm's way. If the growth is infiltrating deeply I cut along the rectum and have never so far wounded this organ. If necessary I cut a portion of one vesicle away and no harm results. There is seldom any serious bleeding, as I have already tied the main vessels; what bleeding does occur is attended to and controlled only after I have finished all the cutting and got the growth away. If you hesitate and try to control bleeding with clamps or swabs implantation is bound to occur. I have often cut away three-quarters of the bladder and half the trigone. In one case I removed seven-eighths of the bladder with half the trigone, yet within a fortnight there was bleeding and clot retention. I opened the bladder afresh and found that in 14 days the new bladder had re-grown so that it could hold over two pints, which confirms in the human the work of Nicolich on the dog's bladder and shows what a rapid power of re-growth the bladder possesses. After an inspection of the deeper parts and a careful hæmostasis I reconstruct the bladder out of the portions left behind. This is the most time-consuming part of the operation, as I prefer to use separate catgut stitches and not a continuous suture. At a good position, which differs in each case, I make a stab wound in the bladder wall, bring the cut ureter through, and fix it there by Coffey's or by Albarran's method. It is impossible to make this stab wound watertight; if one attempts to do so one runs the risk of constricting the ureter. For this reason there is always a small leak of urine into the extravesical space at the side of the rectum for some five or six days. I found that anterior drainage was not altogether satisfactory for this. I therefore modified Squier's operation in the following manner. I make a stab wound into the anterior portion of the ischiorectal fossa on the side of the resected ureter; through this I push a long artery forceps up through the levator ani into the space lying at the side of the rectum and beneath the side wall of the bladder. A tube is fixed in place there and drains away in the most satisfactory manner, from the most dependent position, any urinary leak. I can confidently recommend this step as a most useful technical detail.

Having reconstructed the bladder I make a stab wound into its anterior wall and insert through that a No. 28 Pezzer drainage-tube. I stitch up the abdominal wound as usual, fixing the anterior portion of the bladder above the Pezzer tube to the lower end of the wound, another important detail. I place a small rubber drain beneath the abdominal muscles, as I find there is sometimes a tendency for a temporary leak of urine to occur there for a few days. I have tried fixing a catheter in the urethra, but have given it up in the male as it may lead to urethritis and rigors. In the female it is helpful. I have tried stitching up the bladder completely without drainage and in one case it succeeded—that is to say, the patient passed water naturally from the very first without leakage. Nevertheless, I find there is great wisdom in the aphorism of Hurry Fenwick, "In the waterworks always drain." A small Pezzer drain through the anterior wall of the bladder and a perineal drainage-tube is playing for safety and is, I believe, the wisest form of drainage. At one time I used to wash out the bladder at regular intervals afterwards, but I found that the cases did much better if no lavage was employed at all, and I find it is not needed. Careless lavage may burst the stitches in the bladder wall. Without lavage the urine usually remains perfectly clean, provided that urinary antiseptics are tolerated by the mouth. I employ boric acid in 15-gr. doses accompanied by hexamine in 10-gr. doses exhibited four times a day. Lavage is required for exceptional cases where the urine becomes purulent and alkaline, a rare occurrence. In one case where the urine remained persistently ammoniacal I obtained an immediate amelioration by implanting living lactic acid bacilli into the wound. I remove the Pezzer drain at the end of ten days, by which time the bladder cuts may be expected to be healing up soundly. Urine is usually passed naturally the next day and all the urine is passed naturally by the fourteenth day in the majority of cases. I always strap the upper portion of the abdominal wound from the time of operation. I remove the perineal drainage-tube as soon as all leakage of urine ceases from it. The time varies from a few days to a week or more. It is better to leave this tube in too long than to remove it too early.

I have inspected the results of this operation with the cystoscope months and years after. In many cases it is difficult to say that anything has been done. The ureter looks patent and efficient, save that it is displaced, and there may be seen a linear scar in the bladder wall pulled out a little into the lumen of the bladder. There seems to be little if any tendency to ascending ureteritis and chronic pyelitis, and most of the cases have clear urine.

It is of the utmost importance to estimate the number of red blood corpuscles and the hæmoglobin percentage before proceeding to operation. A patient will not stand this operation with a hæmoglobin percentage of less than 30. In one case, a woman, aged 43 years, operated on early in 1915, had only had hæmaturia for 11 weeks. Blood examination revealed a hæmoglobin percentage of 15 and only 1,000,000 red blood corpuscles per unit of blood. She had a small ulcerating carcinoma above the left ureter, and the anæmia was clearly secondary, not to the loss of blood, but to the specific poisoning produced by the carcinoma cells in the body as a whole. I stitched her husband's radial artery to her median basilic vein and let him bleed into her for 20 minutes. On the table her colour improved and next day her hæmoglobin had risen to 35 per cent. and her red blood corpuscles to 3,000,000 per unit. The following day I performed partial cystectomy with implantation of the ureter and she did splendidly, and writes August, 1922, to say that she is perfectly healthy and has never had any more bladder trouble. Curiously enough some of those who have bled longest and look most anæmic have a fair blood picture. They must have stimulated their hæmopoietic centres to rapid and successful action by intermittent bleeding. Those who have bled little and only for a short time may have a very poor blood picture. To several other cases with profound anæmia I transfused blood indirectly by the citrate method and the results were most satisfactory.

It is also advisable to carry out renal function tests before proceeding to operation, as it aids in giving a prognosis. Nevertheless, in this type of case one kidney is usually acting well enough, though the ureter in the neighbourhood of the growth is often obstructed and dilated so that the corresponding kidney is acting poorly. Such a kidney is more prone to ascending infection after the operation; and it is this dilatation of one ureter which is a definite risk of the operation; so that probably in all cases the cut end of the ureter should be cauterised so as to seal off the mouths of the periureteric lymphatics, the path by which I believe infection ascends. I am convinced that the lumen of the ureter is not the path by which the infection ascends.

It is of interest again to note that of these 28 cases, 21 were males and seven were females. The operation is easier in the male as there is no uterus to get in the way.

In 23 cases one ureter was involved and had to be resected and restitched. Growths of the anterior wall or apex of the bladder are said to be extremely rare. Nevertheless, in the 28 cases I encountered two growths on the anterior wall and two cases of ulcerating carcinoma of the apex. In these there was no need to resect ureters. One case of carcinoma of the apex, where I was able to behead the top of the bladder, stitch it up completely, and the patient passed water naturally from the first and healed by first intention, went on without trouble for two years. Then he suddenly noticed a return of hæmaturia.

Cystoscopy revealed a carcinomatous ulcer on the trigone. I believe that in some of these cases we cure the actual carcinoma for which we operate, but the bladder has made up its mind, so to speak, to become carcinomatous, and I believe that an entirely fresh carcinoma can develop in the reconstructed bladder. In two or three cases I have noted this phenomenon, though absolute proof is not possible. In one or two cases the multiple secondary seedlings were so widespread that I had to be content with removing seven-eighths of the bladder, leaving a portion of the trigone and internal meatus with a few tiny seedlings. These I destroyed completely with open diathermy and the cases did satisfactorily, and have remained well.

As regards physiology my results confirm the experimental work of Nicolich on the dog. I have removed half the trigone and as much as seven-eighths of the bladder, yet the new bladder has grown quickly. The patients can often hold water for four hours by the end of three weeks and pass 12 oz. of urine at a time. In one case, again, I found on reopening the bladder for clot retention at the end of a fortnight that there was apparently a normal bladder just like the original one and it held more than two pints. I shall refer to the work of Delfino later.

These operations throw light on the claims of Steinach to restore youth to age by means of ligature of one or both vasa. Though the vas was ligatured on one side in each of the male cases and on both sides in some, yet it had no effect in making the patient younger. The patient was unaware that this had been done, so auto-suggestion was entirely ruled out, as it is not in the case of Steinach's patients. Two of these cases suffered also from gastric ulcer. One, a woman, underwent operation for gastro-jejunostomy as well as the bladder operation, and is alive and well 11 years later. The other died six months after his bladder operation of acute perforation of the gastric ulcer. An obscure connexion of ulcers in the stomach with vesical bleeding has been pointed out by various authors. Partial or subtotal cystectomy seems, therefore, to possess very little more risk than the old-fashioned operation, but it undoubtedly gives far more satisfactory results and permanence as regards freedom from recurrence. It should therefore be preferred to the old type of operation, and should largely replace the need for considering total cystectomy.

Group 5.—Cystotomy with Local Removal from Inside the Bladder.

This group contained 17 cases of papilloma (simple and malign, single and multiple) treated by the old operation. By the "old" operation I mean that type of operation based on Albarran's description in his book "Médecine Opératoire des Voies Urinaires," where the *anterior wall* of the bladder is opened and the papillomata are dealt with entirely within the bladder by clamping their pedicles and stitching up the cuts with or without open diathermy, and the application of strong silver nitrate to the bladder mucous membrane. This was the operation I had seen carried out in the past with disappointing results as regards recurrence. Fourteen of these operations were performed in the years 1910–13, and three in later years owing to exceptional features which precluded partial cystectomy. Two died, one of peritonitis, one of broncho-pneumonia, so that the risk is not so very much less than that of partial cystectomy. In this group and the last I had three deaths directly due to opening the peritoneum deliberately. This fact has caused me to give up opening the peritoneum, a step which in my opinion adds to the risk, and does not make the exposure any easier but rather the reverse. The chief risk of this operation lies in the amount of time necessarily spent in handling and swabbing the growths. For this reason implantation of seedlings, especially on the cut made into the bladder, is of frequent occurrence. I feel sure, too, that clamping of the pedicle does not ensure the removal of all the tumour cells which have spread either submucously or intramuscularly. The late results as regards recurrence were as follows: Five remained free from recurrence up to 1922; four could not be traced; six recurrences took place in four patients, one being operated on three times, and all these have since died of their disease. At most nine are possibly cured, and five certainly cured, as a result of this type of operation. It is clear, then, that partial cystectomy holds out a better hope of cure than the old operation. The brighter prospects of cure outweigh the greater risks of partial cystectomy.

At one time I tried distending the bladder with air instead of antiseptic lotion, but gave it up, as in one case I ruptured the bladder, and I have known it to cause air embolus. An added advantage of a fairly strong liquid antiseptic for distension as compared with air is that the lotion helps to prevent sepsis and may also hinder implantation of living tumour cells. To perform partial cystectomy on a bladder previously operated on by the old operation is a difficult matter.

(To be concluded.)

THE INTRACARDIAC INJECTION OF ADRENALIN.

By CARL BODON, M.D., Königl. Rath. (Budapest).

The following case of life-saving by an intracardiac injection of adrenalin is quoted in order to point an appeal for general use of the method.

The patient, 56 years of age, residing at Budapest in the same house as myself, returned home on May 28th, 1922, after a short stay abroad, feeling quite well. For a week or two previous to his return he had, on awakening in the morning, experienced a shortness of breath, lasting a few minutes, and never longer than a quarter of an hour. As he felt all right again afterwards he took no notice of it and did not mention it on his return. On the 29th, however, I was roused at 4.30 a.m., as he was feeling very unwell.

Condition on Examination.—I found the patient sitting in an easy chair struggling for breath. His face presented a frightened expression, being very pale and covered with cold sweat. Lips, tip of nose, and finger-nails were cyanotic, hands cold and moist, pulse very frequent and soft, small, unequal, and intermittent. Rapid examination showed the area of heart dullness on both sides to be slightly enlarged. The sounds of the heart were clear but with some loss of distinctness. The respiration was laborious (auxiliary muscles), with an audible crepitus; on auscultation the signs of pulmonary œdema could be found over the lower parts of the lungs. There was a good deal of coughing, with much frothy and bloody expectoration. The patient had a sensation of heavy pressure under his sternal bone.

Unsuccessful Treatment.—I administered 1·5 cg. morphia subcutaneously with no visible effect. As he began to sink rapidly I gave him every minute one to two hypodermic and intramuscular injections of camphor oil (0·20 g.) accompanied by hypodermic applications of ether, caffeine, and one of adrenalin to the number of 8–9 injections. No improvement could be effected, and the radial pulse became impalpable. An attempted intravenous injection of strophanthin and adrenalin proved impracticable; the peripheral circulation was evidently reduced to a minimum and incapable of bearing the injected drugs to the central organs. I resolved to try an intracardiac injection, hurried to my rooms to provide myself with a long needle, and, returning within a few minutes, found that the patient had nearly passed away in the meantime. He lay relaxed and apparently lifeless in his chair, with head fallen backwards; the cyanosis of lips and skin had given place to a deathlike pallor. The eyes were widely open, with largely dilated pupils; corneal reflexes absent; complete loss of consciousness. Shallow inspirations at long and irregular intervals carried the air only as far as the larynx or bronchi. The radial and carotid arteries were not palpable. The systolic murmur over the heart was to be heard intermittently and the diastolic murmur was inaudible ("woodpecker's rhythm": Spechtschlagrhythmus). While I was preparing the injection respiration ceased completely, the patient passed stools and urine involuntarily, and the action of the heart definitely stopped. I considered him to be dead; there was no possibility of doing any harm by an intracardiac injection.

Intracardiac Injection.—I should have preferred to have made the injection into the left ventricle, but the man had an enormous chest, measuring 116 cm. at the level of the nipples. I was without medical assistance, and — I must confess — considerably agitated; under the circumstances I thought it more advisable to make the injection into the right ventricle, this offering less technical difficulty. Everything went more quickly and easily than I anticipated. The needle, thrust cautiously through the fourth left intercostal space exactly at the sternal border, glided easily into the heart. I felt it reach and enter a cavity, and could also feel a light, short contraction caused by the irritation of the needle touching the muscle of the heart. I emptied the syringe, which contained 1 c.cm. of 1 in 1000 adrenalin solution, and extracted it quickly; not a drop of blood was to be seen on the needle or at the site of injection. A few seconds later I observed a steady improvement of the heart beat, which proved regular and effective in less than half a minute. The radial pulse not only regained palpability, but was more satisfactory than when I first examined the patient. Simultaneously with the improvement of the heart's action—that is to say, from half to three-quarters of a minute after the injection, respiration set in with inspirations progressively deeper and more regular. Some minutes later the corneal reflexes returned, and the formerly widely dilated pupils contracted. The extreme pallor of lips and face subsided and was replaced by a dark bluish-red colour, which subsequently lost its cyanotic hue as a deep, snoring respiration became established. The patient did not recover consciousness for two hours. On awakening he remembered nothing of what had happened. Half an hour later, that is two and a half hours after the injection, he could walk with assistance the few steps to his bed, feeling tolerably well but very tired. I gave him a hypodermic injection of camphor oil, and for a few days a daily injection of digifolin and some tabloids of perichol (a combination of camphor, papaverine and cholic acid) on account of the irregularity of his pulse, and kept him in bed. Later I ordered diuretin and large doses of iodine. Up to the end of August—i.e., three months after the injection—the patient felt perfectly well, as he is now in every respect.

The intracardiac injection undoubtedly saved this patient's life.

Previous History.—Details of the previous medical history are of interest. At the age of 16 years irido-keratitis of the right eye left a veiled opacity of the cornea opposite the pupil. In 1906 tonsillitis, acute nephritis with hæmaturia, anuria, and incipient uræmic coma. In 1912 benign glycosuria of fat people (he weighs 110 kg.). The state of his kidneys can be classed as chronic glomerulotubulo-nephritis, with slight albuminuria, a few casts and epithelial cells in the urine, and a slightly raised blood pressure. Some 18 months ago the patient acquired several circumscribed and inflamed superficial thrombi of the veins on his thigh and leg, although he had not suffered from varicosity. I personally could not make much out of them; a specialist attributed them to the patient's chronic renal condition. It took several weeks of compresses and rest in bed to resolve them. Seven or eight months later the patient presented a recurrence of the same trouble. Fortunately I had, in the meantime, looked up the literature of similar cases, and found that Prof. M. Sternberg* had demonstrated them to be venereal. The Wassermann reaction was negative, but, considering the patient's iridokeratitis during adolescence, I gave him daily an intragluteal injection of corrosol (a preparation of corrosive sublimate). After a few injections I noticed a very marked improvement; after 15 injections the thrombosis disappeared completely, although the patient had not been kept in bed at all. The exactness of the diagnosis had been confirmed consequently by the result of treatment.

Diagnosis.—To return to the present nearly fatal attack, I was almost certainly dealing with a disease of the arteries of the heart. It has long since been accepted that a diseased state of the blood-vessels is often caused by diabetes and by Bright's disease (analysis of the urine on the day following the attack showed specific gravity 1013, glucose 1·2 per cent., albumin 0·5 per cent.; the sediment contained some flat epithelial cells, a few old red and some white blood cells, some amorphous salts, and no casts), and it is now known that most cases of primary, progressive arteritis of the brain, kidneys, aorta, and coronary arteries are due to syphilis. This having been a case of very extreme coronary stenosis caused by syphilis, it is to be hoped that the patient will live a good many years, the principal cause of the trouble being easy to treat efficiently. Such cases will be met with more frequently if we are on the look-out for them.

Intracardiac Injections of Adrenalin.

The literature (I regret being unable to refer to English, French, and Italian publications, as since the war they have not been available here, and in the accessible German periodicals I have found no references) of intracardiac injections of adrenalin shows that it was first recommended by Winter[1] against sudden abolition of the heart's action by narcotisation, his experiments on animals yielding very encouraging results. Latzko,[2] in a discussion at the medical society in Vienna in 1909, mentioned that he was the first to try an intracardiac injection on a human being, as early as 1904. In 1910 Läwen and Sievers,[3] of the Trendelenburg Clinic, published their very elaborate and interesting experiments on animals, where they caused suspension of the heart beat by temporary interruption (loop-ligature) of the circulation in the aorta and pulmonary artery. Using strophanthin intracardially the results were in three cases satisfactory, in 11 cases negative. They hold, therefore, that a reviving effect of strophanthin on the heart is *possible but not constant.* (They admit that this opinion does not refer to its application in the shape of an intravenous injection in cases where the heart's action has not yet ceased.) The results were far better with adrenalin. They found that the intracardiac application of the latter drug provoked a contraction of the inner zone of the parietes of the heart which resulted in a stronger systolic contraction and a rise of blood pressure even in cases where, after Bock's method, the vessels of the greater circulation have been replaced by rigid, non-elastic pipes, which proves a *direct action* of the drug upon the heart. Läwen and Sievers divided their experiments into two groups. In the first group the adrenalin was injected into the left ventricle immediately after loosening of the ligature of the artery; the results were very satisfactory. In the second group they waited until they had convinced themselves that artificial respiration with oxygen and massage of the heart were quite useless, before administering adrenalin; in this group the results were less satisfactory, but by no means always fruitless.

In 1915 Szubinsky[4] applied intracardiac injections in three desperate cases on the battle-field. In his first case he gave 2 c.cm. of digipuratum with 10 drops of adrenalin, in the other two cases, advised by Prof. Strasburger, he gave the volumetric quantity of a heart-contraction (Schlagvolumen), viz., 30–40 c.cm. of a 0·8 per cent. salt solution with digipuratum or strophanthin and 10–15 drops of adrenalin. He gave the 30 c.cm. in three successive doses of 10 c.cm. to avoid hyperextension of the cavity. All three patients died, but at necropsy two exhibited fatty pulmonary embolism, and the third had a skull wound and a hæmatoma of the medulla oblongata; nevertheless, in all three cases a temporary improvement was observed—lasting 10 hours in one case, with a transitory return of consciousness. Ruediger[5] reported in 1916 a case at Prof. Brauer's clinic, where a working-class woman, 50 years of age, who had suffered from mitral regurgitation with stenosis and was *in extremis*, was given an intracardiac injection of strophanthin. The woman survived five months and would probably have lived longer under better social conditions. Ruediger also experimented on dogs. For the injection he recommends the second left intercostal space close to the breast-bone (upper part of the right ventricle), sometimes the third intercostal space, because the needle will make here the smallest pendulum movements. Dörner[6] recommended in 1917 the fourth left intercostal space close to the sternum for the injection. His patient had been apparently dead for 20 minutes, but a transitory improvement nevertheless took place. In Volkmann's case[7] (1917) there was hardly any respiration, no patellar or corneal reflexes, no beating of the arteries; over the heart some sparse beatings could be heard. An intracardiac injection of adrenalin diluted with 20 c.cm. physiological salt solution was given and repeated. After the third injection sensation and consciousness returned, but the patient died two hours later.

---

* Syphilis der Kreislauforgane, Med. Klinik, 1920, No. 41.

In 1919 Prof. R. v. d. Velden,[8] the first to employ intracardiac injections systematically in a large number of cases, published an elaborate report of 45 cases treated in the previous 12 years. He resorted to this method only when collapse was so far advanced that intravenous medication was impossible. He used the fourth or fifth intercostal space, two finger-breadths from the left border of the sternal bone. Post mortem he found that his needle had most frequently passed into the myocardium, and not into the cavity. He used alternatively strophanthin, digifolin, digipuratum, camphor oil, caffeine, and adrenalin—never more than 1 c.cm. per dose; latterly he used only adrenalin or strophanthin. In one-third of the cases the immediate results were astounding; pulse and consciousness returned, and on auscultation good heart sounds were to be heard. The best results were yielded in diseases of the heart, myocardiac or valvular trouble. V. d. Velden was not at that time able to produce lasting results; none of his cases lived longer than eight hours.

Similarly an account of a series of cases is given by Walter Hesse,[9] who recommends injection into the left ventricle. He always used strophanthin, 0·5 mg. diluted in 15–20 c.cm. of physiological salt solution. In six of his cases the action of the heart had not quite ceased: heart sounds were feebly audible, and motions of the needle passing through the wall of the heart were felt. In four out of the six the beating of the heart improved visibly within a few minutes, the radial pulsation returned, the hardly noticeable respiration changed into deep breathing, and the patient regained consciousness. In spite of that, death occurred in each case within 20 minutes. Of the other six cases, which were attended by no motions of the needle, three presented slight heart sounds for a few minutes without return of pulse, respiration, or sensation; in the other three cases no reaction was noted. Hesse's cases were of peritonitis with perforation, uncompensated mitral regurgitation and stenosis, uncompensated mitral stenosis, epidemic meningitis, scarlet fever (two), diphtheria, insufficiency of the heart with secondarily sclerotic kidneys, pneumonia, tuberculosis of the lungs, abdominal typhoid fever, and mollities cerebri. The author ascribes his bad results to the fact that he had dealt mostly with infectious cases where the heart had previously been much drugged with stimulants, and he thinks that the best results were to be expected in cases of insufficiency where the heart was not weakened by the use of analeptics.

A successful case of revival from shock due to operation and narcosis has been reported by Zuntz.[10] The patient received 1 c.cm. of adrenalin in the heart four minutes after complete cessation of every heart action. The injection was made in the fourth intercostal space three finger-breadths to the left from the border of the sternum. After 20 to 30 seconds the carotid pulse reappeared, and half a minute later the respiration. At the time of Zuntz's publication (a fortnight after the injection) the patient was still alive.

The question was very thoroughly dealt with, in connexion with four cases, in 1920 by the Swiss Prof. K. Henschen.[11] He gave intracardial and intrapericardial injections, and one case treated in the latter manner was definitely cured. The patient, aged 32, was without pulse and quite unconscious as a result of heavy traumatism. Laparotomy, combined with subdiaphragmatic massage of the heart, had no effect. An injection of 1·5 c.cm. of adrenalin solution, 1 in 1000, was given. The motionless, flabby heart contracted at once and regained its pulsations. Very instructive was his fourth case (gunshot wound of the heart). The heart was laid open and sutured; during the operation the heart muscle contracted very slowly and irregularly and threatened to come to a standstill. One c.cm. adrenalin and 0·5 c.cm. pituitrin were injected into the left ventricle. Instantly a powerful contraction of the whole heart took place, and half a minute later the pulsation of the heart was strong and regular. Unfortunately the patient died on the second day from fulminant pericarditis.

In 1921 Guthman[12] published five cases treated at the clinic for women, Erlangen. In three cases of suspension of the heart's action from peritonitis there was a marked improvement, but the patients died in one, two, and nine and a half hours respectively. In the fourth case a collapse occurred during an operation for extra-uterine pregnancy; camphor, adrenalin intravenously injected, artificial respiration, and direct massage of the heart were resorted to fruitlessly, and six minutes later an intracardiac injection was given. The needle entering the heart showed no motions; after 10 seconds gradually improving heart sounds were perceptible; one minute later the pupils contracted, after another minute the corneal reflex reappeared, and after 11 minutes the first respiratory movement. Four weeks later the patient left the clinic. The fifth case collapsed from operation and hypersensibility to chloroform. The injection was given five minutes after the disappearance of heart sounds. After half a minute a weak heart action was perceptible and after eight minutes the corneal reflex reappeared. The pupils had contracted a little previously. The patient was restored after half an hour and ultimately recovered. The author always employed 1 c.cm. adrenalin and 1 c.cm. strophanthin injected into the right ventricle.

Frenzel[13] had a case of primary stoppage of the heart when producing narcosis with Billroth's mixture. He administered 1 c.cm. of adrenalin solution into the right ventricle, and employed artificial respiration and rhythmical massage of the præcordial region at the same time. The patient was saved, but after the restoration of circulation a coma set in which lasted 19 hours and was complicated with transitory motor excitement (cortical lesion). Frenzel refers to a case successfully treated by Opitz which was followed by a coma of 36 hours' duration.

E. Vogt,[14] of Prof. Mayer's gynæcological clinic at Tubingen, recorded a case where the patient was restored for 24 hours. He injected 1 c.cm. of adrenalin solution, puncturing the third intercostal space on the left side of the sternum, but he objects to that site because of the danger of puncturing the coronary vessels. After detailing the surgical and other indications, he recommended adrenalin. For theoretical reasons, however, in cases where there is a constant elevation of the blood pressure, he recommended hypophysin (hypophysin had already been employed and recommended by Henschen) as well as asthmolysin (a mixture of adrenalin and hypophysin). He held that an intracardiac injection is the simplest and safest proceeding to restart the action of the heart.

F. Schmidt[15] made experimental injections in the left ventricle in 15 cases suffering from incurable deadly diseases (mostly of pulmonary phthisis and inoperable cancer of the womb). He used strophanthin, digipuratum, adrenalin, and strychnine separately and combined. The evidences of impending death were: passive posture on the back with perfect loss of consciousness, stertorous respiration, absence of corneal reflexes, coldness of extremities, and filiform or impalpable pulse. The action of heart and respiration improved in every case after the injection. The radial pulse reappeared and in some cases consciousness returned. One case lived two hours, the greater part 12 to 20 hours, and one over 48 hours. The author admits that in his cases there was no indication for interference, but they had the value of proof as they demonstrated a beneficial effect lasting for several hours or days, even in the case of persons whose vital powers were utterly exhausted.

Remarks.

Having quoted the more conspicuous facts given in the literature, I will arrange them with a view to drawing some conclusions and to expressing my own opinion.

1. *Number of Cases and Lasting Results.*—In the publications within my reach I found over 90 cases. The real number is probably much greater, as a good number of unsuccessful cases probably escaped publication. Lasting results were obtained in 24 cases, my own case included. Schmidt's cases are not included in this number, as they refer to patients in whom the saving of life was a priori out of question. The total given is a very respectable number which cannot pass unnoticed, and which will certainly considerably increase with the results obtained in foreign countries.

2. *Substances Employed and their Mode of Action.*—They were: camphor oil, caffeine, glucosids of the digitalis group, strophanthin, adrenalin, pituitrin, and strychnine. Some authors had recommended administration of these substances diluted in 20–30 c.cm. of physiological salt solution. The preparations of digitalis, camphor, and caffeine were found to be of small efficiency; the latter two drugs have in addition a deleterious effect on the tissues. Strophanthin was preferred by many for its ability to regularise the pulsations, to produce marked contractions of the blood-vessels, and to increase the expulsive power of the heart. Its action is durable, but its intramuscular application is very detrimental to the tissues; moreover, its vasotonic and cardiotonic actions are not as rapid as those of adrenalin. Adrenalin has lately, and deservedly, taken the lead in intracardiac injections where there is no time to be lost, for adrenalin acts instantaneously. It provokes a direct stimulation of the heart by irritating in a specific way the nerve fibres and the end-plates of the sympathetic in the epi-, myo- and endocardium. This is followed by a powerful contraction of the whole muscle of the heart, a dilatation of the coronaries, and in consequence a better flooding of the parietes with blood and a better nutrition of the heart; further, we get a general contraction of the peripheral vascular system with a general elevation of the blood pressure and pulse. *It is not necessary or advisable to give more than 1 mg. adrenalin—i.e., 1 c.cm. of the 1 in 1000 solution,* in view of the possible danger of a tetanic contraction of the muscle with systolic stoppage of the heart. The solutions should be in closed ampullæ, and they ought not to be more than three months old, as they decompose easily. The combination of adrenalin with 20 c.cm. of physiological salt solution, which has been repeatedly recommended, is quite superfluous and would only serve as an obstacle to quick application.

3. *Avoidance of Danger Zones: Technique.*—The danger zones are: (*a*) the region of Spangaroff (upper two-thirds of the sulcus longitudinalis anterior); (*b*) the atrio-ventricular septa; (*c*) the bundle of His-Tawara (these three regions are hardly exposed to lesions during the injection); (*d*) the region of the coronary vessels, which is situated principally along the sulcus and can be avoided with certainty if the injection is not made too high (according to Brünings[16] this danger is mathematically minimised because the area of the coronaries is 1 : 1000 to the area of the free walls of the heart, and v. d. Velden[8] found in his sections reasons to believe that the needle will avoid the blood-filled coronary arteries); (*e*) the internal mammary artery is to be avoided by puncturing closely at the sternal border, because it passes in the height of the second to fifth intercostal spaces, at a distance of 15–17 millimetres from the sternal border.

The instruments necessary are a good syringe and a thin needle 8 cm. in length. The site of puncture should vary with the form and size of the thorax and of the heart and with the position of the diaphragm, but I should advise general adherence to the following rules: In order to reach the left ventricle, puncture in the fourth or fifth intercostal space and, if the heart be very much dilated, in the sixth intercostal space, one finger-breadth inward from the left border of the relative heart dullness—or somewhat inward from the apex beat if the latter can still be found—and cautiously advance inwards and upwards. Arrived at the heart muscle a light pendulum movement is felt (a good sign) and then a harder resistance as the heart muscle contracts from the irritation of the penetrating needle. Somewhat deeper resistance ceases; the needle has arrived at the ventricle, a fact definitely ascertainable by the aspiration of some blood. In order to reach the right ventricle, puncture in the fourth intercostal space, on the upper rim of the fifth rib close to the sternal border. If the diaphragm be lowered, we could choose the fifth intercostal space, but it is better to adhere to the fourth. The needle should pass in a sagittal direction, directed slightly inwards. At the depth of 3·5 to 4 c.cm. the pendulum movement and the resistance of the muscle can be felt, and further on the sudden sensation of the needle arriving in the cavity.

Theoretically it appears to be more useful to inject into the left ventricle because the injected substance reaches the greater circulation more easily than if driven by the thinner muscles of the right ventricle through the lesser circulation. At the same time it is to be noted that Hesse[9] never found post mortem a bleeding into the cavum pericardii after puncturing the left ventricle on account of the thickness of its walls, whereas he found in one out of four cases 20 c.cm. of blood in the pericardial sac after puncturing the right ventricle. The coronary vessels were uninjured. Such an intrapericardiac hæmorrhage could occasionally provoke a mechanical stoppage of the heart by plugging (Herztamponade).

In spite of all this I strongly recommend adherence to the fourth intercostal space on the left sternal border, because the heart lying in this region quite close to the wall of the chest is technically easiest of approach, and the danger zones are avoided with certainty. It is a mistake to regard it as essential that adrenalin should get into the greater circulation. What is required is its *local stimulating action* upon the heart, which can be attained independently of our reaching the right or left ventricle. It has been several times proved that it is quite enough if we inject into the muscle, be it the endo-, myo-, or epicardium. Henschen[11] went so far as to demonstrate that an injection into the pericardium alone is sufficient. Writers also repeatedly record the fact that, aiming at the left heart, and using the suitable method, the needle arrived in the right heart. On the other hand, it remains an open question whether in some cases, where they wished to make the injection in the right heart the needle did not glide through the thin-walled and collapsed right ventricle into the cavity of the left ventricle situated directly behind the former.

4. *The Procedure compared with other Methods: Time and Indications.*—The application of strong electric currents for revivification in cases of sudden death has been discontinued. Artificial respiration is very frequently, and in extremis always, of no effect. Vogt has given Pieri's statistics relating to resuscitation by massage of the heart, showing 20 successful resuscitations out of 76 cases. The operations were: 23 thoracic exposure, 12 transdiaphragmatic, and 41 subdiaphragmatic, massage of the heart. The first two are no longer employed. The use of the third method is very limited, being practicable only where the abdomen is opened. Intravenous injections, infusions, and transfusions are hardly practicable in dying people on account of the collapse of the veins. Their use is strongly opposed by O. Zeller,[17] who experimented on animals, in cases where the pulsations of the heart are imperceptible or had stopped.

Considering all things it seems right to recur to the very simple method of intracardiac injections and the more so as they are applied only in extremis, or very often, as in my case, even later, at a period when circulation and the heart's action had completely stopped. They are applied, as it were, after death to the surviving heart. As to the period of the application, it is established that when the action of heart and respiration have stopped, one should not wait longer than 5–10 minutes. It is true that we sometimes succeed in inducing rhythmical contractions of the heart even some hours after the stoppage of its action. The oft-quoted saying of Vesalius "Cor primum movens et ultimum moriens" proves to be true, but Sand (referred to by Frenzel) proved that, in the brain, degeneration of cells commences three minutes after the cessation of circulation, whereas Batelli † had shown that the resistance of the spinal marrow against anæmia cannot exceed 10–20 minutes. Massage of the heart, also, was unsuccessful whenever the stoppage had lasted longer than 15 minutes, evidently because the reparability of the brain was lost.

The indications were grouped by the various authors in the following manner: (*a*) *surgical:* hypersensibility against chloroform, asphyxia during narcosis, surgical shock, impending paralysis of the heart after operations from peritoneal irritation, resuscitation of the heart during operations upon the heart, or during Trendelenburg's operation for embolism, severe shock from injury, severe and dangerous wounds of the brain, lesions caused by strong electric currents and lightning stroke; (*b*) *obstetrical:* bleeding to death, shock from inversion of the womb, asphyxia pallida of the newborn; (*c*) *internal diseases:* acute disorders of circulation in the heart, diseases of the blood-vessels, infectious diseases, poisonings, congelation.

This list of indications is, in my opinion, unsatisfactory; it creates unnecessary limitations, and cannot be considered complete. So far as I know, nobody has thought of extending the indications to include the very promising and vast field of idiosyncrasies against drugs, and anaphylaxis. It is quite certain that nobody would think of having recourse to this method of treatment in perfectly hopeless cases—for instance, cachexia from cancer or miliary tuberculosis—but it is undoubtedly indicated in all cases where the patient can possibly be saved if a little time can be saved. And here we must not lose hope; we must not say to ourselves "There is nothing to be done here, because this is a case of embolism of the coronary artery, an irreparable degeneration of the myocardium, a heavy valvular trouble, a toxic paralysis of the heart in an infectious disease, a carbonic acid poisoning in pneumonia, &c." In every case where we know that the patient could have lived if some fatal state had not developed—in every case where we are induced to inject caffeine, camphor or the like—it is our duty, whenever intravenous injections prove unsuccessful, and life is dwindling away, to have recourse to intracardiac injection of adrenalin.

Should the last agonies—as in most cases—be protracted, the patient's family should be told that this is a last and perfectly painless experiment to save the dying, but in cases of sudden death, where we have no more than 10 minutes free for action, the doctor has to act without delay, on his own responsibility. There is no use in waiting too long. As I have already explained, the time for action has arrived when agony has set in. Why wait until all manifest phenomena of life have disappeared? It goes without saying that more can be expected from a treatment as long as reflexes, circulation, and respiration exist.

I maintain that it is the duty of our medical schools to counteract aversion from this mode of treatment, which ought to become the common property of all medical men, taught to general practitioners, exactly as other methods of injection are taught. It ought not to happen that, on giving an intracardiac injection, the doctor should become nervous through not having been used to such proceedings. There is room in every medical pocket case for a syringe with a long needle, and for a tabloid or ampulla of prepared adrenalin solution. The technique, as described above, is very simple and easy; it is by no means more complicated than an exploratory puncture of the pleural cavity, and is in any case very much easier than an intravenous injection.

I must state that I expressed the above opinion to Dr. T. v. Verebely, Professor to the University and Director of the first surgical clinic in Budapest, and that he authorised me to state that he is fully in accordance with me as regarding the necessity of making this method generally known. At the same time he told me that he had applied intracardiac injections in three cases with one survival. In one case he demonstrated the mode of operation to his students. I feel convinced that in popularising the method of intracardiac injections we shall be able to save many patients from an untimely death.

EXTREME DILATATION OF THE LEFT AURICLE.

By J. G. EMANUEL, M.D., B.Sc., F.R.C.P. Lond.,
HONORARY PHYSICIAN, QUEEN'S HOSPITAL, AND CONSULTING PHYSICIAN, HOSPITAL FOR SICK CHILDREN, BIRMINGHAM.

The following is a short account of a case in which the heart was of such enormous size as to appear to fill the entire thorax. The great size was due to auricular dilatation and in the main to dilatation of the left auricle. This had dilated, for the most part, in a horizontal direction, so that during life it presented in the right axilla beyond the right edge of the right auricle and was tapped under the belief that it was a pleural effusion. Though such cases no doubt are very rare, it may serve a useful purpose to draw the attention of the profession to them, for in life they present definite physical signs by which they can be recognised and, in fact, these physical signs have been recorded.[1]

The patient, a woman aged 44, came under my care at the Queen's Hospital in September, 1918, suffering from cardiac failure with cyanosis, œdema, and orthopnœa, and she gave the following history:—

History.—Up to the time of her marriage at the age of 33, she had enjoyed good health. She had never had rheumatic fever, or any other illness, though she remembered having growing pains in childhood. During the year following her marriage she underwent hysterectomy for dysmenorrhœa. This operation was followed by an artificial menopause, and after it she suffered from bronchitis every winter, but was not short of breath during the summer months. In 1912, at the age of 38, she underwent a second operation, nephropexy (right kidney), for pain in the right side of the back. After this second operation her health began to fail, and she suffered from shortness of breath on exertion, which gradually increased in severity. Three months after the onset of dyspnœa, œdema of the feet and legs appeared and persisted in more or less marked degree. At the age of 40 she had a "stroke"—left hemiplegia—with sudden loss of consciousness lasting about one hour. At 41 she began to suffer from paroxysmal attacks of palpitations, lasting about two hours. Up to the age of 43 she was able to do her own housework, but from 1917 onwards she was obliged to desist.

Condition on Examination.—When admitted into the hospital, on Sept. 19th, 1918, she presented the appearance of an ordinary case of mitral stenosis, with malar flush, œdema of the legs, cyanosis, and orthopnœa. The heart was of enormous size, a heaving cardiac impulse was conspicuous in the eighth space in the mid-axillary line eight inches from the mid-sternal line and dullness extended from this point to the right anterior axillary line. The upper border of cardiac dullness was at the level of the fourth costal cartilage. There was a well-marked systolic thrill, palpable over the cardiac impulse in the left axilla and also readily palpable outside the right mamma. Although the cardiac impulse was well defined and heaving and the præcordial dullness was so extensive, it was noted that there was no heaving of the præcordial area to the right of the mid-sternal line, and no distension of the jugular veins. At the apex beat both sounds were audible, together with a long, rough, systolic murmur conducted into the interscapular region and a long, rumbling diastolic murmur. At the aortic and pulmonary areas both sounds were audible but weak, and at both areas the systolic murmur was audible. At the tricuspid area no sounds were audible, but a continuous murmur with systolic reinforcement appeared to fill the entire cardiac cycle. The pulse was small, slow, and irregular. The liver was very large, its lower edge being palpable some inches below the costal margin; it did not pulsate. There was a haze of albumin in the urine.

When first I examined the patient, finding dullness over the anterior part of the right chest extending as high as the fourth rib in the right vertical nipple line, the lower border of the liver some inches below the costal margin and the cardiac impulse in the left mid-axillary line, I rather hastily came to the conclusion that the patient had fluid in the right pleura, displacing liver and heart.

As a preliminary to tapping the effusion, I inserted an exploring needle into the fourth space just outside the margin of the right mamma and withdrew a syringeful of bright-red blood. The patient was then radiographed (Fig. 1) and a heart shadow filling the thorax from lateral wall to lateral wall was seen. This led to a more careful consideration of the dullness, which had been interpreted as an effusion of fluid into the right pleura, and the matter resolved itself into making a differential diagnosis between a large hæmorrhagic pericardial effusion, aneurysm of the right auricle or other part of the heart, and extreme dilatation of the heart. Now, the fact that the systolic thrill felt at the apex of the heart, and presumably originating at the mitral valve, was very clearly transmitted to the right chest outside the right mamma was inconsistent with a large pericardial effusion. Further, the absence of expansile pulsation over the dull area to the right of the mid-sternal line precluded aneurysm, unless the wall of the aneurysm was lined, as it sometimes is, by a thick deposit of laminated fibrin. It was, however, unlikely that a systolic thrill would be palpable over an aneurysmal sac whose wall was sufficiently thick to obliterate expansile pulsation. One was therefore led to the conclusion that the dull area to the right of the mid-sternal line was due to dilatation of some part of the heart. The absence of a heaving præcordium in this part, associated with a strong heaving impulse in the left axilla, suggested a thin-walled structure to the right of the middle line with hypertrophied muscle to the left. In other words, the cardiac shadow to the right of the middle line was probably due to auricular dilatation, that to the left to ventricular hypertrophy. That the right auricle could distend beyond the right mamma without marked distension of the jugular veins and a pulsating liver did not appear probable, and one arrived by exclusion at the possibility of the left auricle presenting beyond the right auricle; and though the acceptance of this seemed a little difficult at first, the physical signs showed that it must be so. The systolic thrill and murmur at the apex meant regurgitation of blood from the left ventricle into the left auricle, and as this thrill was transmitted into the right axilla, it meant that the left auricle extended as far as the right axilla; later on this proved to be the case.

Course of Case.—The patient left the hospital on Oct. 14th, 1918, and was seen from time to time as an out-patient. She was not able to do very much, but could walk slowly on the level for short distances. On Feb. 6th, 1920, she walked to the hospital and an electro-cardiogram (Fig. 2) was taken for the first time. This showed a pulse-rate of about 80 per minute, auricular fibrillation, and right ventricular preponderance. The patient was not under the influence of digitalis, so the comparatively slow rate probably indicated some degree of auriculo-ventricular block. Further, seeing that the cardiac impulse was in the eighth space, mid-axillary line, it was a great surprise to read right ventricular preponderance in the electro-cardiogram. This preponderance was confirmed post mortem, and the case is a striking example of our inability to judge by ordinary clinical signs which ventricle is in the main responsible for the production of a hypertrophied heart, as was pointed out by Sir Thomas Lewis.[2]

On May 13th, 1921, the patient was shown at the meeting of the Association of Physicians held in Birmingham, under the title of "Extreme Dilatation of the Left Auricle in a Case of Mitral Stenosis and Possible Tricuspid Stenosis.”

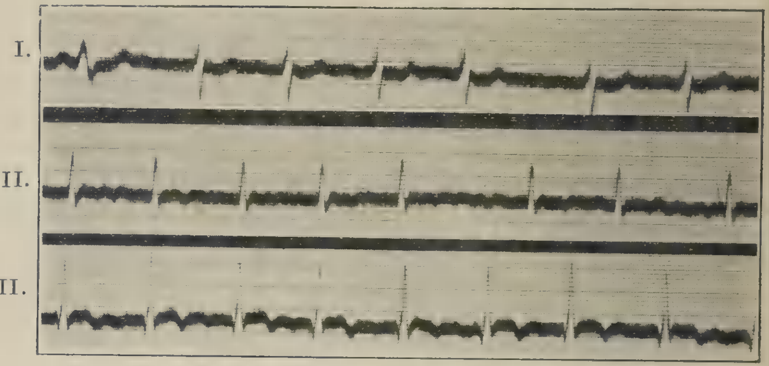
Fig. 2.



Electro-cardiogram (Feb. 6th, 1920) showing: Lead I., a pulse-rate of about 80 per minute; Lead II., auricular fibrillation; and Lead III., right ventricular preponderance.

Readmission to Hospital.—In November, 1921, she became confined to bed and on May 11th, 1922, was readmitted to Queen's Hospital. She then exhibited intense cyanosis, extreme dyspnœa, œdema of legs, thighs, hands, arms and trunk, ascites, and slight jaundice. The pulse was slow, 60 to 80 per minute, the cardiac physical signs much the same as those already described. There was œdema of the lung bases, enlarged liver, and incontinence of urine. She died two days after admission.

Autopsy.—The pericardial sac was found to extend from one side of the chest to the other, being separated from the lateral chest walls by a very thin layer of intervening lung. There were dense pericardial adhesions over a triangular portion of the left auricle, the triangle having for its apex the inferior vena caval opening, and for its base, a line extending from the openings of the right to those of the left pulmonary veins. The heart was of enormous size; its maximum transverse diameter measured 12 inches (see Figs. 3 and 4). The enlargement was mainly due to the increased size of the auricles, which were so distended as to resemble a thin membranous sac, to which the ventricles were attached as mere appendages. The left auricle was at least twice as large as the right, and protruded a couple of inches beyond the right border of the right auricle. After shrinkage in preservatives the left auricle held 40 oz. and the right 20 oz. of water. The inter-auricular septum was intact. There was moderate hypertrophy of the ventricles, the right being dilated as well as hypertrophied, the left hypertrophied without dilatation. The mitral valve was stenosed, and formed a narrow slit, the tricuspid valve was dilated. The aortic and pulmonary valves were not examined.

In Fig. 4 the letter A lies in the middle of the triangular area of pericardial adhesions.

Comments on the Case.

If this case were an isolated pathological curiosity, it might be thought unprofitable to attract attention to it. The facts are otherwise. Sir Isambard Owen has described a similar case in a woman of 40[3] who had suffered from symptoms of cardiac failure for 18 years. In this case the left auricle extended 4½ inches to the right of the right auricle, and during life was tapped under the impression that a pleural effusion was displacing the heart to the left, for the apex beat was in the eighth space, posterior-axillary line. The case occurred at St. George's Hospital, and the author refers to two other similar cases, the specimens of which are in the museums of St. Bartholomew's[4] and University College Hospitals.[5] In the Brompton Hospital museum there is another very similar specimen.

---

[3] Clinical Society Transactions, 1901, xxxiv., 183; 1902, xxxv., 147.

The question arises as to what is the underlying cause of this extreme dilatation, and attention is first focused on the mitral valve. Have we here an extreme dilatation of the left auricle, minor degrees of which are common in cases of mitral stenosis? The specimen at Brompton Hospital would support this contention, for it was associated with a buttonhole mitral valve and tricuspid stenosis was present as well. In the St. George's Hospital case, however, the mitral orifice admitted four fingers, the edges of the valves were thickened, and the chordæ tendinæ short and thick. In the St. Bartholomew's Hospital case the mitral orifice admitted three fingers easily, the edges of the valves were thickened. In the University College Hospital specimen the mitral valve does not seem to be seriously diseased; it is described as a little thickened at the free border. The condition of the mitral valve, therefore, cannot, in itself, be a cause of the dilatation.

I take it that the dilatation is an expression of a pathological condition that may affect the mitral valve and myocardium at the same time, and that condition is a carditis, frequently of rheumatic origin. This view is supported by another fact. In each of these five cases the pericardium was the seat of a former infection. In the St. George's Hospital case we read, "No general pericarditis, but the two layers of the pericardium adherent over the left auricle." In the St. Bartholomew's Hospital case we find "Fibrous adhesions with calcareous flakes over the left auricle." In the University College Hospital case the pericardium was described as "universally adherent and calcified." In the Brompton Hospital case we have "some pleuro-pericardial adhesions and dense pericardial adhesions over the lower part of the left ventricle." In the Queen's Hospital case there were dense fibrous adhesions over a large triangular area of the left auricle. The dilatation is not the result of these pericardial adhesions in the sense that the adhesions act mechanically by traction on the auricle, for the dilatation is uniform, and in the Queen's Hospital case, at any rate, the adhesions are partial. The pericardial adhesions, like disease of the mitral valve, are merely the permanent indications of an erstwhile carditis, the brunt of which, for some unknown reason, fell on the myocardium of the auricles. The auricular walls thus weakened by an attack of myocarditis gave way under the intra-auricular pressure. Now, in mitral stenosis as in mitral regurgitation, the pressure in the left auricle is increased, and the clinical indication of this is the accentuated pulmonary second sound and the hypertrophy of the right ventricle. It is this increased intra-auricular pressure acting on the left auricle, the wall of which has been weakened by an attack of myocarditis, which has given rise to the extreme dilatation here met with. The right auricle is not affected to anything approaching the same extent, because so long as the tricuspid valve remains competent, the right auricle is not submitted to any increased pressure. Tricuspid regurgitation is a late event in cases of mitral stenosis. The left auricle, on the other hand, is submitted to the increased pressure as soon as stenosis or regurgitation of the mitral valve is established.

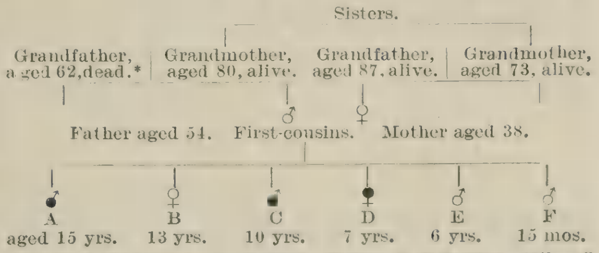
HAYWARDS HEATH HOSPITAL.—The annual meeting of the King Edward VII. and Eliot Memorial Cottage Hospital at Haywards Heath was held on March 15th. A resolution was passed authorising the completion of the incorporation of the institution. The feature of the year 1922 was the installation of an electrical plant. The hospital had been closed for some considerable time for repairs and alterations, but despite this the deficit on the year was only £210.

HEREDITY IN ALCAPTONURIA.

BY C. FIRMIN CUTHBERT, F.R.C.S. EDIN.

IN view of the interest which attaches to the heredity of alcaptonuria, the history of the following family appears to be worthy of record. The father and mother are both English. They are first-cousins, the father's mother and the mother's mother being sisters. The parents know of no case of the kind among their forbears. They have had six children, all of whom are alive and in good health. There have been no miscarriages or stillbirths. None of the children exhibit any structural malformation. Neither parent is alcaptonuric; of their six children, three (A, C, D) exhibit the anomaly. The following is the family tree.



* Died suddenly of "heart failure," following fall off hay-rick.

The eldest boy came under observation when a baby of a few months old, as the mother noticed that his napkins were stained. The stains were at first pink, as was also the urine, but both napkins and urine turned black on exposure to air. The pink urine of this child only lasted about two years, and none of the other children have apparently shown signs of pink urine.

The parents live on a farm, and have been naturally not very willing to give information about their apparently healthy children, but eventually I have made the necessary investigations and obtained reliable details. The woman has been attended by a nurse in her confinements, and it has been impossible to collect any urine passed for the first time by a newly-born baby, or to find out how soon after birth the napkins have become dark by the exposure of urine to air. The urine of the affected members of the family yields all the characteristic reactions of alcapton urine. It darkens on exposure to air, and eventually becomes black; reduces Fehling's solution, and gives a momentary blue colour when a drop of a dilute solution of ferric chloride is allowed to fall into it.

In view of the observations of Söderbergh[1] that the subjects of alcaptonuria may yield Wassermann reaction apart from any other evidence of syphilitic taint, and apparently owing to the presence of homogentisic acid, specimens of blood were taken from five members of the family, but in every case W.R. was negative. The blood of the youngest child, F, was not taken on account of the difficulty of passing a sterile hypodermic needle into any vein sufficiently prominent at the bend of the elbow, or any other part. It has not been possible to test the effect of the administration of tyrosin, which in some of Söderbergh's cases led to a change from a negative to a positive W.R. This is to be regretted, since urine contains homogentisic acid which is formed from the tyrosin and phenylalanin groups of the protein molecules; but the difficulty of carrying out this treatment can be understood from the fact of the necessity of administering 5 g. doses of tyrosin to each of these children, and then having a W.R. done on the bloods at the end of 24 hours.

The noteworthy points in the family tree are:—

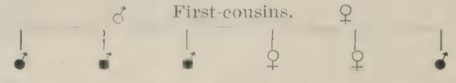
1. The high proportion of affected members, in excess of what is to be expected in the case of a Mendelian recessive character, such as alcaptonuria almost

---

[1] Neurologisches Centralblatt, 1914, p. 24.

certainly is. 2. The consanguinity of the parents, which has been a feature of a large proportion of alcaptonuric families. 3. The excess of males over females, which is a noteworthy feature in this and allied inborn errors of metabolism.

Debenedetti records a family with an even higher proportion of alcaptonuric members.[2]



In the collaboration of this report I have had the great advantage of the advice and assistance of Sir Archibald Garrod, and it is at his instigation that I wrote out these notes of this family.

Gloucester.

PARAFFINUM LIQUIDUM.

A REPORT ON THE ACTION OF LIQUID PARAFFINS OF WIDELY VARYING VISCOSITIES.

BY H. B. RUSSELL, M.D., M.R.C.P. LOND.,

AND

P. C. BRETT, M.B., B.S. LOND.

THE lubricant action of liquid paraffin is now generally recognised, and its use as a mechanical laxative has grown to an enormous extent of late years. Because we were aware of these facts and knew that the preparations universally obtainable, although probably answering the tests of the British Pharmacopœia, nevertheless differed widely in viscosity, we thought it worth while to make extensive clinical trials with paraffins of widely varying viscosities. In THE LANCET of August 12th, 1916, it was emphasised that all liquid paraffins sold should be of British Pharmacopœia standard, and earlier in the same journal (1915, ii., 761) it was pointed out that many samples of liquid paraffin sold to the public, although answering the British Pharmacopœia tests, varied widely as regards viscosity—the extremes being 296 and 71—and that it was very improbable that paraffins of such extremes of viscosity would give precisely similar therapeutic effects. Referring to the great importance of viscosity, the conclusion was arrived at in THE LANCET (1915, ii., 884) that " a good working physiological viscosity would probably be in the neighbourhood of the figure of 105."

Because we, too, appreciate the fact that viscosity is such an important factor (since lubrication is by no means ideal unless the lubricant is intimately mixed with the fæces), and because from casual observations we were under the impression that a viscosity of 105 was far too low for a really satisfactory liquid paraffin, that we made the following investigations, in which were used : (*a*) Liquid paraffin low viscosity (130), specific gravity 0·8718 ; (*b*) liquid paraffin high viscosity (230), specific gravity 0·8902.

Method of Investigation.

The method of investigation was as follows : 44 cases were treated for about three weeks each with paraffins of the two viscosities mentioned—130 and 230. The low and high viscosities were given in each case for alternate weeks ; in about half the cases the low viscosity was given first, in the other half the high, and the doses varied from 1 to 3 oz. in the 24 hours. Careful attention was paid to the results, the following points being especially noted : (1) the laxative action ; (2) the amount of leakage, if any ; (3) the *tendency* to leakage, which latter was shown by marked evidence of paraffin imperfectly mixed with the stools. Thirty of these cases were normal pregnant or lactating women, and here it was impossible to watch the results of treatment, so that we had to rely on verbal information ; the other 14, however, were hospital medical cases suffering from a variety of complaints. Some of these patients were entirely confined to bed, others were up and about for the greater part of the day. In these 14 cases we were able to watch closely the results of an aggregate of 169 days of treatment and to examine 212 stools, and the following is a summary of our observations :—

Leakage.—No leakage in 11 cases—Nos. 2, 3, and 6 to 14.

Case.	Low viscosity.	High viscosity.
1	Slight on 2 days, ½ oz. t.d.s.	—
4	,, 2 days, 1 oz. b.d.	1 day, ½ oz. t.d.s., this being the first day after the change from the low viscosity.
5	,, 1 day, 1 oz. b.d.	2 days, 1 oz. b.d., first two days of treatment.

Paraffin very Conspicuous in Stools.—Not evident in 5 cases—Nos. 1, 2, 6, 7, 12.

Case.	Low viscosity.	High viscosity.
3	2 days, 1 oz. t.d.s.	—
4	1 day, 1 oz. b.d.	1 day, 1 oz. t.d.s., first day after change from low viscosity.
5	2 days, 1 oz. b.d.	1 day, 1 oz. b.d.
8	3 ,, 1 oz. t.d.s.	1 ,, 1 oz. t.d.s.
9	5 ,, 1 oz. t.d.s.	—
10	3 ,, 1 oz. t.d.s.	1 ,, 1 oz. t.d.s.
11	2 ,, 1 oz. t.d.s.*	—
13	4 ,, 1 oz. t.d.s.	—
14	3 ,, 1 oz. t.d.s.	—

* Patient very ill, passing blood and mucus.

—	Total number of days' treatment in 14 cases.	Leakage.	Paraffin conspicuous in stools.
Low viscosity	85	5	25
High viscosity	84	3	4

The paraffin of high viscosity had a slightly more laxative action than that of low viscosity, and the result of the investigations shows that there is decidedly more tendency to leakage with the low viscosity than with the high, for although definite leakage was detected in 5 instances only out of 85 with the low viscosity as against 3 out of 84 with the high, yet the fact remains that in 25 instances out of 85 with the low viscosity the paraffin was so imperfectly mixed with the stool as to be evident, whereas with the high viscosity this state of affairs was noticed in only 4 out of 84 instances.

From the foregoing series of investigations it is clear that a paraffin of viscosity 230 gave more satisfactory results than one with a viscosity of 130, and in our opinion it is preferable always to use a paraffin of high viscosity. The mean of the viscosities of the two paraffins used in our trials is 180, and we strongly recommend that a viscosity standard of certainly not less than 180 should be adopted. The viscosity figure is the time in seconds taken by 50 c.cm. of oil maintained at 100° F. to flow out from a Redwood viscometer.

Clinical and Laboratory Notes.

TRACHEOTOMY IN AN INFANT.

BY EUSTACE THORP, O.B.E., L.R.C.P. EDIN., L.R.F.P.S. GLASG., D.P.H.,

ASSISTANT HEALTH OFFICER, SUNDERLAND.

THE following case is interesting chiefly by reason of the difficulty in breathing experienced after the tracheotomy tube was removed the second time, although no obstruction was present.

A male child, aged 9 months, was admitted to hospital on July 13th, 1922, suffering from laryngeal diphtheria of two days' duration, no antitoxin had been administered. Tracheotomy was necessary and was performed (very high and practically a laryngo-tracheotomy) by a practitioner in the neighbourhood before my arrival ; on arrival I gave 18,000 units of antitoxin in three doses. Two days later the child was doing well except for a profuse mucous discharge and the coughing of pieces of membrane. This discharge has continued to date, varying in consistence only. Repeated attempts to remove the tube failed, plugging of the tube brought on urgent symptoms immediately. There was no laryngeal paralysis and apparently no stenosis or granulations, but there was slight ulceration of the trachea, nervousness was present, and the child always objected to the removal of the tube, and would endeavour to remove plugs or coverings put on with a view to re-establishing breathing by the nose. About the middle of September such breathing was observed, and the child frequently coughed up mucus through the mouth.

---

[2] Il Policlinico. 1920, xxvii., p. 1379.

On Oct. 2nd I determined to clear the matter up; difficulty was being met with in replacing the tube, and I opened up the wound, and performed a lower tracheotomy, incising the trachea for about an inch, making a thorough examination, removing any small granulations found. I passed a Belloc's sound through the larynx to the mouth, making sure that these passages were normal; I then put in the tracheotomy tube, and commenced treatment as a new tracheotomy. On the third day I removed the tube altogether and the child became very nervous, endeavouring to remove the coverings from the wound and to establish breathing by the trachea. Difficult breathing with retraction of ribs came on, and he slept little; but knowing that the trachea and the larynx were clear I ignored the apparently urgent symptoms, crediting them to the child's nervousness. In a day or two he began to settle down, and breathing became normal. He is now doing well.

The child was discharged in November. The wound healed and he has been frequently seen since; the mother states that he is very well, though at times he can produce a dyspnœa at will, but having been warned of this peculiarity she was never alarmed at it. Swabs after the first tracheotomy gave the following results: July 25th, positive; August 8th, negative; 22nd, positive; 28th, negative; Sept. 2nd, negative; 11th, negative.

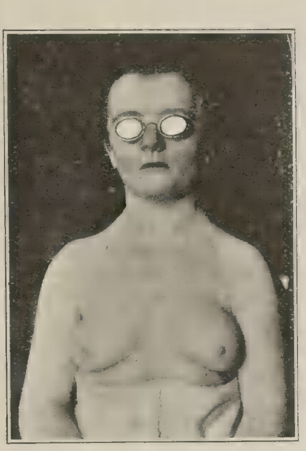
The case is interesting, not only from the rather unusual length of time during which the tube was retained and because of the difficulty of breathing, but also because of the nervousness of the child. A certain amount of nervousness is to be expected when the tube is first removed, but in this case the degree observed was remarkable. I see the child frequently now, and he appears to be entirely free from any dyspnœa. The latter recurred at times, during the four months following the patient's discharge from hospital, when he was excited or crying. There is now no abnormality of any kind present.

Sunderland.

A CASE OF
CRANIO-CLEIDO DYSOSTOSIS.

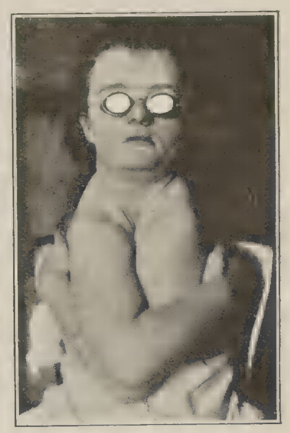
BY ALBERT B. COCKER, M.R.C.S., L.D.S. R.C.S. ENG.,
AND
H. SEWELL SIMS, M.B., B.CH., B.A.O. R.U.I.

FIG. 1.



Normal appearance of the subject.

FIG. 2.



Showing mobility of shoulders.

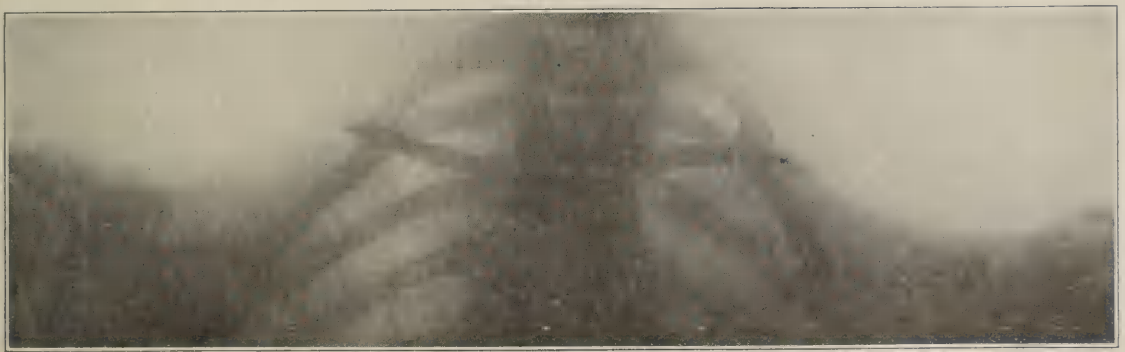
THIS case of cranio-cleido dysostosis has several points of interest. The patient is a healthy-looking girl, aged 16 years, height 4 ft. 10 in., weight 7 st. Her normal appearance is shown in Fig. 1.

Family History.—Youngest of 11, one died at 11 months of meningitis, the other nine all healthy and no deformities. Mother alive and healthy, father died eight years ago of cardio-vascular disease, aged 54. No history of deformities on either side of family.

Personal History.—Full-term child, but very small, no serious illnesses. Pulsations over the head could be seen and felt until she was about 14 years old; up till this time she often complained of headaches, which have disappeared. Pulsations cannot now be felt. Intellect above the average, can play piano, do typewriting and shorthand. Does not complain of any weakness about the shoulders and did not know the clavicles were missing until told about 12 months ago.

Present Condition.—Forehead high, square, and slightly projecting, frontal and parietal eminences prominent, and depression between frontal eminences well marked. There is a large flattening corresponding to the anterior fontanelle and a smaller one corresponding to the posterior fontanelle, and flattening along the sagittal suture. Only a few teeth are erupted. In the upper jaw both permanent laterals, the four premolars, and left second molar are erupted. In the lower jaw two temporary incisors, left temporary canine, and second temporary molar are erupted. Where the teeth are not erupted the alveolus is thick and firm, and most of the unerupted teeth can be felt. The four first permanent molars were extracted on account of being septic with enlarged glands in the neck; these teeth were hypoplastic and since the extractions two months ago the enlarged glands cannot now be felt.

FIG. 3.



X ray photograph of shoulder-girdle, showing clavicles, represented at the sternal end only by bones one-third of their normal length.

Clavicles.—Both clavicles are represented by about one-third of their sternal end; these can be felt, and the free ends moved about among the soft parts of the supraclavicular triangle (Fig. 3). The remarkable mobility of the shoulders, which can be made to touch each other anteriorly, is shown in Fig. 2.

We are much indebted to Dr. Robert Simpson and Dr. David Morrow for the illustrations.

Palmer's Green, N.

Medical Societies.

ROYAL SOCIETY OF MEDICINE.

A general meeting of Fellows was held on March 13th, Sir William Hale-White, the President of the Society, being in the chair.

Mr. J. E. Adams read a paper on the

Urgent Need for Education in the Control of Cancer.

He said that while the Registrar-General's returns showed that cancer was increasing, much patient work by members of the medical profession had left us still unable to discover the cause of cancer. The purpose of this paper was to advocate better education of the general public in the early signs and symptoms of cancer in order that they might be induced to present themselves for treatment at the earliest possible stage of malignant disease, when there were reasonable prospects of cure by surgical means. Mr. Adams said that the Americans had given us a lead in this respect by establishing in 1913 the American Society for the Control of Cancer, with the object of disseminating knowledge concerning the symptoms, diagnosis, treatment, and prevention of cancer, of investigating the conditions under which cancer is found, and of compiling statistics in regard thereto. This society, which included many medical men whose names were known on both sides of the Atlantic, had a separate organisation in every State, and issued pamphlets and leaflets in simple non-medical terms broadcast to the public. Lectures were also given, and during the last two years a " Cancer Week " had been organised, during which an intensive campaign was carried on in the public press, by addresses in churches and theatres, by posters and films in picture palaces. Ten million people were supposed to have received the vital facts of cancer control during this week. The objection that such a campaign would produce an alarming spread of cancerophobia was not the fact. Mr. Adams had the authority of the President of the American Society, Dr. Powers, for stating that cancerophobia hardly existed in his own city of Denver, Colorado, which had been very thoroughly instructed. Some educative work had already been done by Mr. C. P. Childe and some medical officers of health, but while these were efforts in the right direction they failed to reach the mass of the population. The British Red Cross Society had both the means and the machinery for conducting a public campaign and would be willing to coöperate with a committee of the Royal Society of Medicine if they were asked to do so. He thought it possible that the Ministry of Health and perhaps also life assurance companies might help.

Three Resolutions.

Mr. Adams then formally proposed the following resolutions :—

1. That it is desirable that the public should be given more information as to the early signs of cancer and the prospects of cure by immediate treatment.
2. That the British Red Cross Society be asked to conduct this publicity campaign by means of lectures and pamphlets.
3. That the Council of the Royal Society of Medicine be requested by this meeting to nominate a standing committee to supply information to the British Red Cross Society suitable for wide dissemination and the education of the public.

The resolutions having been seconded, Mr. C. P. Childe said that a change in the attitude of the public towards this matter was indicated by the fact that the publishers of his book, who in 1907 would not allow the word " cancer " to appear on the title-page, had withdrawn their veto when asking him to produce a second edition recently. He maintained that the word " cure " might reasonably be used in connexion with cancer, for provided cases came to operation sufficiently early there was every prospect of securing for the patient many useful years of freedom from recurrence. Simple information could be supplied to the public by the clergy, nurses, health visitors, &c., by the press, and, as was already done at Portsmouth and elsewhere, by the medical officer of health.

Sir A. Stanley referred to the large organisation built up by the British Red Cross Society during the war, much of which was still in existence. As president of a hospital he knew something of the incidence of malignant disease, and he thought that the machinery and funds of his Society could not be better employed than in the work of educating the public under the direction of the Royal Society of Medicine.

Education to Begin with the Medical Profession.

Lord Dawson thought that education should begin with the medical profession. More attention was now devoted to the early signs of cancer at the teaching schools, but the general practitioner when cut off from the accessory means of diagnosis at the teaching hospitals soon became discouraged and apt to let early cases go on until the diagnosis was unquestionable and the disease, in consequence, well advanced. What was needed was better spread of the ancillary means to early diagnosis at cottage hospitals and small centres all over the country. Better doctors would result and from better doctors more sensible patients. He saw a very real danger of cancerophobia from a campaign on the American lines and thought that we had already had experience of what might happen from the unfortunate results of the V.D. campaign—for which under the special circumstances there was perhaps some justification.

Dr. Herbert Spencer suggested that, in order to convince the public and the profession of the success of operative treatment of early cancer, the Society should collect statistics of cases free from recurrence, say 20 years after operation for proved cancer, and, if possible, exhibit the patients. As regards the diagnosis of cancer in gynæcological cases, his branch of the profession had been much handicapped by the meagre allowance of beds at the teaching hospitals. Gynæcologists themselves were often ignorant of the frequency of cancer of the body of the uterus. He urged the necessity for better certification of the cause of death and for the performance of post-mortem examinations on all cases dying in institutions ; he was inclined to agree with Lord Dawson that education should begin with the medical profession and as to the probable effect of a press campaign in producing cancerophobia.

Sir Napier Burnett said that the British Red Cross Society was only anxious to take up the suggested campaign if the Royal Society of Medicine would call upon them to do so and would direct their efforts. They were already conducting popular lectures on " How to Keep Well," and the call for this work was increasing so that they had difficulty in finding sufficient lecturers for their present work. The Royal charter of this Society indicated a dual purpose : (1) the mitigation of suffering and (2) the prevention of disease. Such a campaign as had been suggested would, he thought, fairly come under the latter heading.

Mr. Cecil Rowntree thought that previous speakers had been looking at the disease from a wrong standpoint. He pointed out that no good result or cure would be achieved by bringing many forms of malignant disease to early operation, such as cancer of the œsophagus or periosteal sarcoma of the long bones, and that the dissemination of public knowledge of these diseases would merely result in needless mental suffering. What was more needed was proper organisation of cancer research to enable the energies of many workers to be better directed and to prevent the waste by overlapping that occurred at present.

Dr. A. Mearns Fraser said that he was impressed by the apparent increase in cancer in his borough (Portsmouth), and in 1913 he issued leaflets to the public in an attempt to cut down some of the needless mortality from ignorance. Surgeons in the borough thought that his campaign had already achieved good results. He did not agree with some of the American methods, but considered some forms of publicity a necessary and proper part of the work of a health department.

Dr. C. W. HUTT (M.O.H., Holborn) wished to point out the importance of the maternity and child-welfare centre in any campaign against cancer.

Dr. A. LAPTHORN SMITH agreed that education of the medical profession was a first essential, and referred to a number of precancerous conditions to which insufficient importance was attached by general practitioners.

Dr. S. MONCKTON COPEMAN said that the Ministry of Health already had a departmental committee on this subject with powers to coöpt, and urged that if the Royal Society of Medicine took up this matter they should coöperate with the Ministry of Health.

Dr. JOHN SHAW considered that the statistics of cancer proved that surgery was never justified and on these grounds objected to any form of propaganda which urged operation for cancer.

On being put to the meeting, the numbers then being small, the resolutions were carried with two dissentients.

SECTION OF OPHTHALMOLOGY.

A MEETING of this section was held on March 9th, Mr. A. L. WHITEHEAD (Leeds), President of the section, being in the chair.

Case of (?) Spring Catarrh.

Mr. CYRIL WALKER (Bristol) showed a case for diagnosis. It was that of a woman, aged 37, who had warty growths on the eyelids. At the age of 18 she had tuberculosis of the right elbow; she had many operations on it during its long course, but eventually the sinus closed and left her a good useful arm. She had also had repeated attacks of colitis, which were regarded as tuberculous. No lung disease had been detected. Mr. Walker first saw the patient seven years ago, when the growths on the lids were not so widely distributed as now. On scraping, he found the tissue more cartilaginous than he had expected. Pathological examination of the scrapings did not support the idea of tuberculosis; there were epithelial ingrowths. The application of sulphate of copper did not seem to have any effect either way. A smear showed marked eosinophilia, which favoured the view that it might be spring catarrh, though in Bristol that disease seemed to be very rare. He asked whether radium or other form of irradiation was the correct treatment. Recently the pre-auricular glands on both sides had become enlarged.

The PRESIDENT said he would have diagnosed this, without hearing the history, as spring catarrh. He advised the use of radium.—Mr. T. HARRISON BUTLER said he had had two patients with spring catarrh treated by radium. Two of them did extraordinarily well; the third not quite so well. He saw, in the East, tesselated forms of spring catarrh. He advised that the treatment by radium should be carried out at the Radium Institute.

Tumours of the Optic Nerve.

Mr. HUMPHREY NEAME read a paper on this subject, supplemented by photographs and micro-photographs of two cases of the condition which had been under his care in the last two years. The first was that of a boy aged 14. At the age of 8 the patient's mother noticed that one eye was more prominent than the other. Vision did not become defective until a late stage. When Mr. Neame saw the case in 1920 the proptosis had been slowly increasing since 1915, and at the latter date the eye possessed only perception of light. In spite of the marked proptosis, the eye movements were good. Nasal examination revealed nothing which would account for the proptosis, and a skiagram of the skull failed to reveal any abnormal shadows in the orbital region. In 1921 Mr. Neame removed the tumour by splitting the internal canthus back to the orbital margin. On blunt dissection, a short piece of optic nerve was found immediately at the back of the eyeball. The tumour was not completely removed; there was an escape of glairy fluid from the back of the tumour, and the tumour largely collapsed. The after-result, except for some hæmorrhage into the orbit soon after the operation, was uneventful. Histologically, the optic nerve appeared to be normal. The pial sheath was practically intact on both sides. Mr. Neame referred in detail to the pathological findings in similar cases by Mr. A. C. Hudson. He thought this case was one of gliomatosis.

The second case reported by Mr. Neame was that of a woman, aged 79, whose eye had been blind for many years. Probably her visual defect preceded the proptosis. Complaint of considerable pain determined the removal of the eye. As a mass was found behind, a modified exenteration of the orbit was carried out. The optic nerve was much degenerated, and there was a great increase of fibrous tissue. The growth proved to be mainly in the subdural space, with a spreading into the dural sheath, splitting that sheath into layers. As she had cataract, no view of the fundus was obtained. Mr. Hudson had laid stress on the fact that this type of tumour, which arose in the endothelium and arachnoid space, tended to spread into surrounding tissues, whereas a gliomatosis remained relatively local. The optic nerve in this case had suffered a very marked change, and part of the growth showed cells arranged in whorls. There were a number of spaces between the growth cells, and this feature strongly supported the diagnosis of endothelioma. The subjects of endothelioma were distinctly older than those of gliomatosis. In the former the exophthalmos generally preceded interference with vision, because the growth did not primarily invade the optic nerve. In gliomatosis, however, the nerve was destroyed first, and limitation of movement of the eye was not so great as in endothelioma.

Mr. TREACHER COLLINS said great help in the diagnosis was obtained by noting the progressive character of the hypermetropia, following the pressure on the back of the globe. When removing a growth by Krönlein's method, so as to save the eyeball he stitched the lids together, because of the anæsthesia persisting for some time afterwards. In one case the growth had extended back through the optic foramen into the skull, but no cerebral symptoms followed, and the child lived many years afterwards, showing that the malignancy of these cases was not great. He did not think he would do a Krönlein on a future case, but would be content to do what Mr. Neame had done, cut the outer canthus, which allowed any optic nerve tumour to be felt with the finger, and the resultant disfigurement was less than after a Krönlein. He discussed the pathology of these growths.—Sir JOHN PARSONS thought a proportion of the cases which were called glioma were really fibromatosis.

Mr. NEAME, in reply, agreed as to the value of stitching the lids. He did it in this case, and the sutures held for a week, and probably had much to do with the success in saving the eye, as there was early corneal ulceration.

Mr. F. A. WILLIAMSON-NOBLE read a paper on

Orbital Endothelioma.

He said he had seen two cases of the condition during the last two years. The first case was that of a girl, aged 15, who was seen by Mr. A. Levy 12 months ago. The history was advancement of the right internal rectus, tenotomy of right external rectus in 1913. There was proptosis of the right eye for two months. The movement out and down was very limited, and slightly limited in the upward and inward directions. The pupil was inactive, the disc somewhat pale, and the vision was reduced to perception of fingers at a distance of 4 feet. The eye was enucleated, and the growth removed piecemeal. When portions of the growth were embedded in paraffin, the structure resembled that of carcinoma of the breast. The slide exhibited showed a large amount of fibrous tissue, enclosing spaces containing numbers of large endothelial cells with round nuclei. The cells showed a tendency to form spaces, a characteristic of endotheliomata; there was also a marked tendency to the formation of whorls. In the large whorls, those which had existed longest, the cells had undergone complete degeneration, showing as a plaque of fibrous tissue. These features brought the tumour into the endothelioma category. This tumour closely invested the optic nerve, and pressed upon it, causing vacuolation of it, as shown in the slide. The tumour seemed to have arisen from the endotheliomatous cells wrapped round the strands of the pia arachnoid. High magnification showed definite continuity between the endothelioma cells and the endothelial cells on the inner surface of the dura. Still, this appearance might be produced by infiltration from without.

Mr. Williamson-Noble's second case was that of an orbital tumour in a boy, aged 3½ years, and he also was under the care of Mr. Levy. There were chemosis, dilated inactive pupil, some swelling of the disc, and proptosis in a forward direction. When the eye was enucleated the orbit was seen to be occupied by a solid mass. There was much swelling of the nerve head, but the physiological pit was still present. The tumour was received for examination in pieces, and at first it seemed to be of a complex nature; some parts contained bone, some showed apparently normal cartilage, and deeply-stained cells occurred in some parts, less in others. Some bleeding had occurred into its substance. It seemed to arise from the lacrymal gland, but the gland cells appeared normal, and they seemed to have no neoplastic activity. Sections did not seem to reveal any evidences of involvement of the optic nerve in the growth, nor involvement of dura or pia. The diagnosis seemed to be either sarcoma, teratoma, or endothelioma. He inclined to regard it as periosteal chondro-sarcoma.

Mr. **LEVY** said the patient with the mixed sarcoma lived six months, his death then being due to intracranial extension of the original growth. No postmortem examination was allowed.

Mr. M. S. **MAYOU** referred to two cases of endothelioma of the orbit which had been under his care. The first, in a child, consisted of very large cells packed together, with practically no fibrous tissue. The child died while in hospital. The tumour filled the whole middle fossa of the skull, perforating the skull through the temporal bone and bulging outside in the temporal region. The other was in a girl, aged 22, whose orbit was cleared out. Under the microscope it, like one of Mr. Williamson-Noble's cases, looked like scirrhus of the breast. The patient lived 18 months. No recurrence took place in the orbit, but there was disease in the frontal region. These growths produced a variety of appearances, due to the degeneration so liable to take place in them.

Mr. R. A. **GREEVES** considered the second case a mixed tumour. In the orbit mixed tumours arose mostly from the neighbourhood of the lacrymal gland, though not from that gland itself. With this view Mr. **TREACHER COLLINS** agreed.

Mr. B. **CRIDLAND** related a case which came to him and was operated upon by the late Sir Victor Horsley. In that instance the growth came through the sphenoidal fissure, and the operation had therefore to be a very extensive one. He thought the ophthalmic surgeon should not deal with these cases unless he was prepared to do a big intracranial operation if such were necessary.

Mr. **LESLIE PATON** referred to a case of endothelioma of the orbit in which the submaxillary gland was involved, and the nature of the growth was the same in both cases. Then the glands down the anterior border of the sterno-mastoid got involved, then those in the axilla, and all had growth of the same nature. The woman died with a huge mass of mediastinal glands, and they also presented a picture identical with the others. The transference had taken place along the lymphatics.

The **PRESIDENT** showed a specimen of a tumour, apparently of the optic nerve, which he had removed. When the eye had been removed he found three olive-shaped bodies behind, but the optic nerve was not involved; it was pushed on one side. Probably it was a neuroma of the ciliary nerve.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION.

A MEETING was held at the Elizabeth Garrett Anderson Hospital on March 13th, Dr. **LOUISA MARTINDALE**, the President, being in the chair.

Dr. **FRANCES HUXLEY** read a paper entitled

Ante-Natal Diagnosis.

She detailed the clinical signs of pregnancy and the dates at which they can usually be detected. She then described the various "grips" which she is in the habit of using for estimating the size of the pelvis, the lie of the child, and the relation between the size of the head and pelvis. She discussed the date of engagement of the head in primigravidæ and multigravidæ respectively, and emphasised the importance of estimating the size of the fœtus as the best guide to its maturity. In discussing the lie of the fœtus she pointed out some of the dangers and difficulties in doing version in breech presentations, and she also pointed out that the site of maximal intensity of the fœtal heart is generally to be found below the umbilicus in such cases rather than above, as is usually taught.

A discussion followed in which Lady **BARRETT**, Prof. L. **MCILROY**, Dr. M. **RORKE**, Dr. I. **RUSSELL**, and others took part.

MANCHESTER MEDICAL SOCIETY.

A MEETING of this Society was held on March 7th, Sir **WILLIAM MILLIGAN** being in the chair.

Dr. J. C. **BRAMWELL** read a paper on

Some Aspects of Heart-Block.

He said the introduction of the electro-cardiographic method has thrown much light on the mechanism of the heart beat, and the disorders to which that mechanism is subject in disease. Some of the more recent work had an important practical application to the clinical problem of prognosis. In its mildest form heart-block is characterised by a prolongation of the interval which elapses between the contraction of the auricle and ventricle. It differs therefore only in degree from the normal mechanism which serves to prevent simultaneous contraction of these two chambers, such as occurs in some cases of "nodal rhythm."

In addition to the more familiar forms of partial and complete block, lesions of one or other of the main branches of the A-V bundle give rise to characteristic alterations in the ventricular complex of the electro-cardiogram. This is due to the fact that the excitation wave is forced to pursue an abnormal course, and is delayed in its passage to the affected ventricle. In certain cases of grave myocardial disease a form of electro-cardiogram is met with which resembles that of branch bundle lesions in the increased duration of the initial ventricular deflections, but differs from the latter in its smaller amplitude, and in a peculiar notching of the Q-R-S group. Rothschild and Oppenheimer consider that this type of electro-cardiogram is characteristic of a lesion affecting the terminal arborisations of the Purkinje system. Whether this hypothesis will ultimately prove to be correct is uncertain, but the records of this type are undoubtedly of grave prognostic significance. Complete heart-block is frequently compatible with a comparatively active life, and it is during the transition stages before complete heart-block has been finally established that syncopal attacks are most liable to occur. During periods of severe and repeated Stokes-Adams seizures the prognosis may appear to be well-nigh hopeless, but in many of these patients the attacks subsequently disappear completely, or become less frequent, and a surprising degree of recovery is attained.

In certain cases of cardiac irregularity the normal heart rhythm is interrupted by long pauses. On account of its resemblance to A-V block this condition has been termed "sino-auricular block," on the hypothesis that the excitation wave arises in the S.-A. node but fails to reach the auricle. This hypothesis is likely to require modification in the light of further knowledge, but serves for the present to bring the condition into line with the more familiar forms of cardiac arrhythmia.

Dr. Bramwell's paper was illustrated by electrocardiographic records from patients treated in the Manchester Royal Infirmary during the past three years, whose after-histories had been followed up to the present time.

NORWICH MEDICO-CHIRURGICAL SOCIETY.

Exhibition of Cases and Specimens.

A MEETING was held at the Norfolk and Norwich Hospital on March 6th, Dr. ARTHUR CROOK, the President, being in the chair.

Dr. A. J. CLEVELAND read notes of a case of gastric ulcer with hæmorrhage into the suprarenals, which was only diagnosed post mortem. He pointed out that hæmorrhage from the stomach often occurred without ulcer, and that bleeding cases were not favourable for operation. Hæmorrhage into the suprarenals was a recognised cause of sudden death, which occurred in this case.

Dr. H. J. STARLING showed a case treated by intravenous peptone therapy. The patient was a farm labourer and maltster, aged 55, who had never had any previous serious illness. On Oct. 24th, 1922, he had a severe quinsy which confined him to bed for 14 days. On Nov. 23rd he was attended by Dr. J. K. Howlett, of Dereham, who found him very ill, with œdematous swelling of both legs and with a purpuric eruption over both legs and some parts of the body. The swelling of the right leg subsided quickly, but that of the left persisted and increased, soon showing several blebs which assumed a gangrenous appearance. On Dec. 14th an incision was made into a large gangrenous patch on the dorsum of the left foot which appeared to give fluctuation, but no pus was found; the patient did not feel the incision. On admission to hospital on Dec. 15th the pulse was rapid and feeble, and the left leg much enlarged and tender. On the 17th the right foot had become œdematous, and the skin below the external malleolus was discoloured. On the 18th the right leg was pitted up to the top of the thigh. The patient was obviously much worse, and at 1 P.M. 0·3 c.cm. peptone was given intravenously; at 2.30 P.M. a severe rigor occurred with a temperature of 99·4° F. On the 19th patient looked and felt better in every way. The pallor had largely disappeared, as had also the œdema of right leg, except for a little at the foot. The external saphenous veins were thrombosed and much thickened in both legs from the thigh downwards. A leucocyte count showed 7800 white corpuscles. On the 21st 0·5 c.cm. peptone was given intravenously. There was no rigor and little rise of temperature until the next day, when it rose to 101·8°; the white count was 11,700. On the 26th 3 c.cm. peptone, the last dose, was given at 1.15 P.M., and at 2.30 P.M. a severe rigor occurred with a temperature of 102°. On the following day the leucocyte count was 19,000. By this date the patient's condition no longer caused anxiety. The swelling of the left leg had gone and the necrotic area was separating away from healthy granulation tissue. On Jan. 6th, 1923, the leucocyte count was 18,000, and on the 30th it was 12,000. W.R. negative, blood culture negative. There now remained only a clean-looking oval ulcer on the dorsum of the left foot 3 or 4 in. long by 1 or 2 in. in width. Dr. Starling said that in his opinion the chief use of peptone therapy was in cases of inflammation when the leucocyte count was low.—The case was discussed by the PRESIDENT and by Mr. A. J. BLAXLAND and Dr. V. H. BLAKE.

Dr. E. B. HINDE showed a girl of 18 with marked atrophy of the left leg. His attention was called to the condition by the girl's complaint of pain in the left knee, where he found a slight thickening above the knee and a considerable diminution in the measurements of the thigh and calf as compared with the other leg. Under X rays no sign of bony disease was shown. The girl leads an active life and is fond of dancing. Dr. Hinde suggested that the condition was either the result of infantile paralysis or possibly a local tuberculous condition in the synovial membrane, but asked for suggestions as to diagnosis or treatment.—The PRESIDENT suggested that the condition might be due to a birth injury.—Dr. BLAKE thought it might be a psychical condition, and that the patient should be encouraged to continue leading an active life and to take no notice of her leg.

Mr. J. BURFIELD showed a woman, aged 61, from whom he had removed a huge ovarian tumour as well as several gall-stones. The tumour contained cartilage and was a teratoma, probably congenital. His medical colleague, Dr. Sidney Long, had given his opinion that the patient, who had auricular fibrillation, would stand the anæsthetic, and that her dyspnœa and other symptoms were probably due rather to pressure of the tumour than to the cardiac condition. The patient stood the operation exceedingly well, and the condition of her heart had improved since.

This case gave rise to a discussion as to what constituted a contra-indication to operation under a general anæsthetic.—Dr. LONG thought that the condition of the lungs was most important, and Dr. STARLING laid stress on the previous condition and medical history of the patient, but the general opinion seemed to be that in serious surgical emergencies there was hardly any contra-indication to operation if the patient was not actually moribund.

Dr. L. BURVILL-HOLMES showed a case which he had provisionally diagnosed as encephalitis lethargica. The patient was a girl, aged 3, who had had pneumonia twice, and mumps six months ago. A month ago she had a febrile attack lasting two days; temperature 101° F.; she vomited once; had no physical signs. She did not appear to have been quite well since then, but nothing definite occurred till 14 days later when she became drowsy, sleeping all day. A few days later she commenced staggering in her gait, always staggering towards the right. There was some loss of power in the hands. She had improved somewhat the last few days, though she was still drowsy and still staggered slightly. There were no eye symptoms or ocular paralyses. Dr. Burvill-Holmes had not notified the case, as he was not sufficiently sure of the diagnosis.

The following specimens were shown:—

Mr. A. J. BLAXLAND: Malignant tumour of kidney, causing hæmaturia as the only symptom, removed from a man of 53. Dr. H. R. MAYO: Fibro-adenoma of left breast, weighing 4½ lb., from a patient aged 88, with microscopic slide of same. The PRESIDENT: Stillborn fœtus and placenta from a case of albuminuria of pregnancy. Mr. T. W. HANCOCK: A double ileal intussusception removed post mortem from a child dying of broncho-pneumonia a month after an operation for intussusception. Mr. J. BURFIELD: X ray plates showing comminuted fracture of humerus treated with Parham and Martin's bands.

BRIGHTON AND SUSSEX MEDICO-CHIRURGICAL SOCIETY.

A MEETING of this Society was held on March 1st, Dr. D. W. LIVINGSTONE, Vice-President, being in the chair.

Dr. WALTER BROADBENT read a paper on

Pneumonia and Its Complications.

He discussed differential diagnosis, different types of the disease, and the various complications which might ensue, giving illustrative cases. In regard to treatment, he was strongly of opinion that the patient should be moved as little as possible by nurses, since auto-inoculation occurred so readily. For lobar pneumonia with high temperature he thought the ice-bag good. Vaccines, if of the right type of pneumococcus, were useful if given on the first or second day. In delayed resolution and after empyema autogenous vaccines hastened cure. He had excellent results from the use of the Pasteur Institute antipneumococcic serum, and also from Pane's serum. Medicinally he thought aspirin and quinine valuable, also the creosote and potassium iodide mixture, and for extremely poisoned cases Warburg's tincture. If the pulse-rate was up to 100 digitalis should be given, and if up to 120 hypodermic strophanthin. Hypodermically camphor was valuable.

Dr. BROADBENT also showed a blood slide from a baby 5 weeks old with a spleen reaching well below the umbilicus; this was a case of severe leucocythæmia, the white cells almost equalling the red.

Mr. H. F. SEYMOUR showed a case of

Facial Hypoglossal Implantation for Facial Paralysis.

He said that C. K., aged 11, had been treated for chronic otitis media of long standing for about a month without success. A radical mastoid operation was then performed. Facial paralysis came on three days later (although the facial nerve had not been injured at the operation) and recovery did not take place, even after five months, in spite of massage and electrical treatment. An implantation of the facial into the hypoglossal nerve was then undertaken. Some enlarged lymphatic glands below the tip of the mastoid process were cleared and the nerve was found bound up in the connective tissue of the periadenitis, as it came out of the stylo-mastoid foramen. Consequently the trunk of the nerve had to be divided at its point of entry into the parotid gland. It was dissected out and the hypoglossal isolated; a nick was then made into the latter and the facial trunk drawn by fine catgut sutures into it. The junction was then buried in the posterior belly of the digastric muscle. After five months passed the patient began to use the risorius muscle, and the levator labii superioris and orbicularis oris came into action. The eye shut quite well, but the frontalis portion of the occipito-frontalis was still paralysed and there was no sense of taste on the right side of the tongue anteriorly. The tongue moved normally and the facial movements were daily improving.

Reviews and Notices of Books.

CONFLICT AND DREAM.

By W. H. R. RIVERS, M.D., D.Sc., LL.D., F.R.S. With a Preface by G. ELLIOT SMITH, F.R.S. London: Kegan Paul. 1923. Pp. 195. 12*s.* 6*d.*

IN this posthumous work Dr. Rivers has maintained criticism of psycho-analysis at an intellectual level, with no trace of that emotional influence which so often intrudes into discussions of the subject. He tells how Freud's scheme of dream-interpretation left a most unsatisfactory impression on his mind, but that he made no great progress in dream-analysis or in the clinical utilisation of dreams until he had a dream himself which went far to convince him of the truth of the main lines of the Freudian position. He analysed by an individual method his own and his patients' dreams, finding in the majority of cases wishes, conflicts, and anxieties arising out of recent experience. Though ready to acknowledge (p. 59) that deeper analysis would in many cases have led to earlier and deeper experience, yet in the record of dream analyses by Freud himself (p. 98) he finds "a striking similarity with those I have analysed with respect to the recency of the conflicts they reveal." After this, one is hardly prepared to read (p. 144), "I believe that . . . . the importance of early experience has been greatly exaggerated by Freud and his followers," but the opinions of Dr. Rivers were in a fluid state, and if he had been spared to revise the manuscript of these essays such apparently differing views might have been reconciled.

He doubts the scientific value of free association in dream analysis; although it may serve as an instrument of diagnosis and treatment yet there is no proof that it necessarily leads up to experience which has taken any direct part in the causation of the dream. In the dream he finds an attempt at the solution of a conflict rather than the fulfilment of a wish, and instead of attributing transformation and disguise to the censorship he would regard them as necessary consequences of the infantile character of the dream. The war dream he considers to be a regression, especially when terrifying animals appear, and as these dreams fail to find explanation on psycho-analytical principles one regrets that he was not able to carry the analyses more deeply. It must be admitted that, measured by psycho-analytical standards, his analyses stopped short of completeness. Dr. Rivers provides evidence from his own dreams that the symbols to which a universal sexual significance is attached may at least in some cases bear a meaning of a different kind—and psycho-analytical orthodoxy would not dispute this evidence; but evidence has also led him to believe that the symbols often have this sexual meaning (p. 177). That the symbolism should be innate and universal to mankind is, however, a theory to which Dr. Rivers as an ethnologist cannot subscribe, and he prefers to regard the symbolism as a common tradition which reaches the individual in early years.

The book contains many intimate touches that indicate the personality of the writer. Characteristic is his admission (as on pp. 109 and 110) that his material is of a special kind and his conclusions are therefore not final; this admission disarms the only serious criticism called forth by the book, which in psychological language can be described as free from affect, and is written in the true spirit of scientific criticism. To this spirit Prof. Elliot Smith pays, we think, insufficient tribute in his preface; when he says that it prunes "repulsive excrescences" and "introduces for the first time principles of logic and consistency and a closer connexion with reality," he does, perhaps, less than justice to the manner of the book, though Rivers would himself have appreciated the studious moderation.

RESPIRATORY SYSTEM.

Maladies de l'Appareil Respiratoire. Tome II. Traité de Pathologie Médicale et de Thérapeutique Appliquée. By Several Authors. Edited by EMILE SERGENT, L. RIBADEAU-DUMAS, and L. BABONNEIX. Paris: A. Maloine et Fils. 1922. Pp. 392. Fr.20.

THE first thought on glancing at the table of contents of this text-book on the treatment of the diseases of the respiratory system is: How can this ambitious scheme be adequately developed in so limited a space? The subjects dealt with in this volume are asthma, emphysema, pulmonary sclerosis and atelectasis, pneumoconiosis, pneumo- and broncholiths, hydatid cysts, malignant disease, and various diseases of the pleuræ and mediastinum. A big programme indeed, but it is well executed in spite of the authors' self-inflicted brevity.

It is instructive to compare this work with a similar one, such as Powell's and Hartley's "Diseases of the Lungs and Pleuræ." Authors of text-books have sometimes been accused of systematised plagiarism, of just copying, with only enough variation to give the latest production a thin varnish of originality. Such a conception seems impossible when the two works referred to are contrasted. Though the subject is the same, it is dealt with in quite different ways, and even the elementary facts on which theories can be built do not always tally. Let us take, for example, such a condition as rheumatic pleurisy. The French authors devote some space to this subject, committing themselves to well-defined opinions such as the examinee loves. The English authors are more wary, and barely mention the existence of rheumatic pleurisy, thus tacitly admitting that very little is known of the condition. A subject on which the English authors leave much unsaid is that of the effects of gassing. The French authors give a very helpful account of this product of the war, and, like American observers, they have come to the conclusion that gassing has seldom anything to do with the genesis of pulmonary tuberculosis. Persons who in childhood or later in life have suffered from tuberculosis or other diseases of the lungs may indeed be more adversely affected by gassing than those whose lungs had previously been healthy. But it has struck the authors that while tuberculosis was rife among the French soldiers returning from captivity under gas-free conditions, it was rare among the soldiers who remained in the fighting line exposed to various gases. The fate of the soldier who has been badly gassed appears often to be tragic; at the age of 25 or 30 he may find himself irrevocably condemned to the lot of an old man with emphysema and chronic bronchitis, and it is little wonder that he becomes a neurasthenic wreck.

The authors are to be congratulated on having provided an admirable digest of our knowledge, new and old, of the diseases of the respiratory system, and their review is as comprehensive as it is succinct.

A SYNOPSIS OF MEDICINE.

Third edition. By HENRY LETHEBY TIDY, M.A., M.D., B.Ch.Oxf., F.R.C.P.Lond., Assistant Physician to St. Thomas's Hospital; Physician to the Royal Northern Hospital. London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd.; Bristol: John Wright and Sons, Ltd.; Toronto: The Macmillan Co. of Canada, Ltd. 1923. Pp. 985. 21*s.*

THE fact that a new edition of this book is called for almost every year speaks for itself. Few critics are more severe than the medical student, and if they tend to judge such a book chiefly from the utilitarian standpoint, it is but fair to say that even their teachers would find it hard to suggest improvement in this carefully compiled précis of medicine. The new edition contains articles on veronal and cocaine poisoning, Vincent's angina, cyclical vomiting, cœliac disease and sprue, none of which appeared in the previous edition. Renal and gastric efficiency tests are detailed, the Van den Bergh test is quoted, and a brief account of insulin is included. One could wish that the account of gastric physiology had been more carefully written. If it be necessary for the student in his final years to memorise such subjects, at least he should be fed with facts which the modern physiologist accepts as accurate. But the reader must search hard to discover mistakes in detail, and we feel that Dr. Letheby Tidy will enjoy in this edition a repetition of his previous success.

LEHRBUCH DER PERKUSSION UND AUSKULTATION.

By Prof. ERNST EDENS. Berlin: Julius Springer. 1920. With 249 illustrations. Pp. 498.

IT is seldom necessary or desirable to review a book more than a couple of years after its publication. Whether it be a matter for regret or rejoicing, it is certainly true that many scientific books are out of date within two years of their appearance, and a late review, if it were candid, would be of the nature of an obituary notice. Prof. Edens's book does not belong to this class; practically all his work bears the stamp of durability. For this reason, and because a concatenation of adverse circumstances has prevented an early review of his book, we take the opportunity to make good this omission.

The work is divided into three sections. The first is concerned with the examination of the respiratory system, the second with that of the cardio-vascular system, and the third with that of the abdomen. Prof. Edens teaches the elements of physics before he makes his pupils associate sounds and sensations with morbid processes. The author reproduces Sahli's graphic system for recording the most common pulmonary signs—a system which has most undeservedly fallen into disuse. It is, indeed, a great pity that this system has not been internationalised and standardised in the sense that the Turban-Gerhardt classification of pulmonary tuberculosis has received universal recognition. In the section dealing with the cardio-vascular system, the account of modern sphygmographic research is supplemented by excellent illustrations. The illustrations, by the way, add greatly to the value of this book. Some are chiefly of historical interest, such as the one showing Laennec examining the chest of a consumptive in 1816 at the Hôpital Necker. Others are of more material value. All have been selected with discrimination, and many are coloured.

Altogether a first-rate book, full of knowledge pleasantly transmitted.

FRAMBŒSIA TROPICA.

By R. L. SPITTEL, F.R.C.S. Eng., General Officer in Charge of Venereal Clinic, General Hospital, Colombo; Lecturer in Clinical Surgery, Ceylon Medical College. London: Baillière, Tindall and Cox. 1923. Pp. 59. 5*s.*

THIS is an excellent little book. The clinical description of yaws is very good, and evidently represents the result of years of close clinical study in Ceylon, where the disease still flourishes in the low-lying jungle districts. The descriptions are verified by a series of well-selected photographs illustrating all stages of the disease. The contrast between this disease and syphilis, with which it has much in common, is well brought out and summarised in a table at the end of the book. Yaws does not affect the central nervous system; it is never congenital; the mucous membranes and eyes are unaffected, and the primary sore is extra-genital. The effect of salvarsan upon all stages of yaws—primary, secondary, and tertiary—is almost miraculous; the specificity of the drug appears to be more striking than it is in syphilis. The prevention of yaws, the author says, is indubitably easier than that of syphilis. Entirely free from stereotyped views, this little book will be appreciated by students and practitioners alike.

PRACTICAL PHYSIOLOGY.

By G. V. ANREP, M.D., D.Sc., Senior Assistant in Physiology, University College, London; and D. T. HARRIS, M.B., B.S., B.Sc., Assistant Professor of Physiology, University College. London: J. and A. Churchill. 1923. Pp. 212. 10*s.* 6*d.*

THIS is the best attempt yet made to produce a satisfactory book on practical physiology, possibly because the authors have both studied and taught at such an admirable centre of research in experimental physiology as University College. Dr. Anrep is, in addition, a pupil of Prof. Pavlov, of Petrograd. Dr. Harris's ability in expression and draughtsmanship contributes much to the value of the book, but he is, we think, almost cursed with a passion for devising new forms of apparatus. He has gone to the length of inventing a special slide-rule for converting millivolts of E.M.F. in hydrogen electrode measurements into terms of pH. The course consists of a large number of experiments on frogs, mammals, and man, and there are also instructions to demonstrators and advanced students enabling them to carry out more difficult demonstrations or exercises. Some of the exercises are of a chemical description, and there is also a chapter giving an outline of experiments on pharmacology. There are a few unimportant errors—one of these, we think, is the statement on p. 14 that the dose of urethane for anæsthesia is 0·1 g. per kilo of body-weight. The dose should be much greater than this, unless other anæsthetics are used as well. The last sentence in the book, which terminates with a paragraph on the B.Sc. (Honours) course, reads: "All students are required to engage on a piece of individual research." If this sentence is to be taken literally the demonstrator's life will not be a happy one.

THE COPPER BOX.

By J. S. FLETCHER. London: Hodder and Stoughton. 1923. 5*s.*

SOME of our serious and busy readers are not superior to the allurements of sensational fiction—sharing, apparently, this taste with important cabinet ministers—and we have before now expressed the view that the relaxation to be obtained by reading a good story, sufficiently good to hold the interest, but calling for no serious mental reaction, is distinctly beneficial as well as very pleasant. Mr. Fletcher's novels here fill the bill; he is ingeniously inventive, he is humorous, and, above all, his stories are coherent—given the premises, which may be quite improbable, the sequences pursue a logical course to a reasonable conclusion. We recommend this last work to novel readers on these grounds.

THE OUTLINE OF LITERATURE AND ART.

London: George Newnes, Ltd. In 24 Fortnightly Parts. 1*s.* 2*d.* each.

THE "Outline of Literature and Art" is planned on the lines of Mr. Wells's "Outline of History," and Prof. Arthur Thomson's "Outline of Science," and bids fair to rival the success of these valuable works. It is edited by Mr. John Drinkwater and Sir William Orpen, R.A., and proposes to "summarise 3000 years of beauty and of dreams."

The major portion of the work will be concerned with English literature, where every branch receives notice from the days of Chaucer, through the great Elizabethan age, and the seventeenth and eighteenth centuries, down to our own day. It is also intended to embrace an account, even though a cursory one, of Continental and American literature, and the attempt will be made to deal with this vast material in a plain and direct manner, so that the reader may form a just estimate of the masterpieces of the past, and be able to form comparative judgments on the literature of our day. In a similar way the new "Outline" proposes to deal with Art, though the method of instruction will here be simpler, as no attempt will be made to criticise or appraise the great artists, either of the past or present. This section, judging by the four parts which have already appeared, will be sumptuously illustrated by reproductions of many of the greatest pictures of the world, and from them, and the notes explanatory of their designs, characteristics, and messages the reader will be helped to form intelligent opinions. This section obviously labours under the disadvantage which the artist must always have as against the author; we usually judge the latter by his actual words, and the former through the medium of a copy. But our National Gallery—now the finest representative collection of pictures in the world, despite its weakness in one or two schools—contains a large amount of the pictures adduced as striking instances of the advance of Art.

The first four parts comprise, under Literature, the story of Homer, and the story of the Bible; and under Art, the invention of oil-painting, the wonder of the Renaissance, bringing us down to the Venetian school. The story of the Bible is contributed by Canon Barnes, whose detailed history of the wonderful compilation expresses the new theological views.

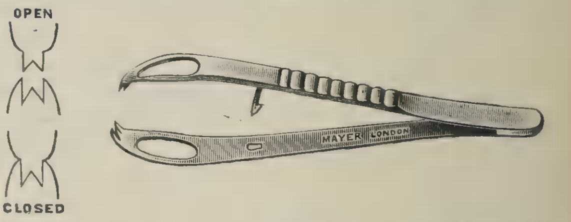
JOURNALS.

MILITARY SURGEON, February, 1923.—In this issue Captain James Chambers Pryor, Medical Corps, U.S. Navy (author of "Naval Hygiene"[1]) has a very suggestive and valuable paper on the Medical Officer and the Employees' Compensation Act. He points out that when a naval medical officer is appointed to do duty in a dockyard he has not only to treat the sick and the injured, but to do all he can to prevent sickness and injuries, and gives some useful and pertinent advice on those lines. He observes, too, that it has been shown that 75 per cent. of injuries were due to carelessness, to prevent which he recommends that the service shall adopt the system followed by some farseeing industrial companies who pay their supervisors a bonus inversely proportioned to the cost of the disabilities from accidents occurring among the group of men supervised by each of them. He goes further and desires that a challenge trophy shall be annually competed for by all the dockyards, and won by that yard which shows the best results of safety effort and accident prevention.—Major A. T. Cooper and Captain A. J. Vadala, Medical Corps, U.S. Army, report encouragingly on carbon tetrachloride as the treatment for hookworm infection. They dealt with some 40 cases in the State of Georgia, where about 14 per cent. of the population are infested. Three c.cm. of CCl_4 are administered in a single dose, preferably before breakfast; no special previous preparation and no subsequent dietary restrictions are required. The results "with only one dose of the drug have been 100 per cent. cure." Thymol treatment generally necessitated two courses and on an average 12½ days in hospital; oil of chenopodium usually required nine days in hospital. Carbon tetrachloride cures at once, but patients are generally kept two days so that their stools may be examined and found negative on the second day; this vermifuge cured several cases that had resisted the other treatments mentioned, and set up no inconvenient after-effects.

New Inventions.

THE "MADAM" ARTERY FORCEPS.

ARTERY forceps with a male jaw having only a single point which engages with the double points of the female jaw possesses several inconveniences, and the surgeon who uses such forceps sometimes finds that he has only a point in his hand with which to touch the bleeding vessel and shut the other jaw of the forceps upon. The result of the first attempt to seize the artery at the vital spot is often failure, and the forceps has to be taken off and reapplied. None of the artery forceps at present in use is a perfect instrument, and it occurred to me that if the ordinary artery forceps could have the male jaw improved by giving to it the power to clasp the female jaw and have femininity superimposed upon it by having two additional points laterally which projected beyond the central point, the problem of the perfect artery forceps would be solved. The accompanying illustration shows the jaws both open and closed of an instrument which I have had made. The upper or female jaw has the shape of a W, and the lower a combination of two N's, one the reverse way to the other. The lower jaw also shows a W which encloses the upper W. It is really two points into three, but having the central point of the three receded. I have tested the "Madam" artery forceps practically and have found it a useful addition to the everyday tools of the surgeon.



Messrs. Mayer and Phelps, of New Cavendish-street, London, W., are the manufacturers.

FRANCIS STANHOPE PITT-TAYLOR, M.B., Ch.B.
Blackpool.

[1] Reviewed in THE LANCET, 1919, ii., 832.

THE LANCET.

LONDON: SATURDAY, MARCH 24, 1923.

THE WORK OF THE DENTAL BOARD.

The new Dental Board is in the interesting position of having an enormous number of newly-registered though unqualified dentists, as well as a very large new income. We have already announced the appearance of the Dental Register for 1923, which contains 12,762 names, an increase of about 7000 on the average number registered for the last ten years. Of these, 4984, or 39 per cent., are names of graduates and licentiates in dental surgery. Of the remainder, nearly 1000 still hold their registration under the Dentists Act, 1878; and 6721, or 53 per cent., have been registered as dentists in 1921 under the new Act, without additional medical or surgical qualification. The accounts and the minutes of meeting of the Dental Executive Committee of the General Medical Council held on Feb. 26th, show a total income from registration fees of £62,260, and a surplus for the year, after paying the whole of the Dental Board expenses and five-twelfths of the expenses of the General Medical Council, of £34,285. Of this income the sum of £27,000 received for original registration will, of course, be much reduced in this and succeeding years, since further additions to the Register will be relatively few in number, and there is a reasonable feeling among qualified men that the annual fee should be reduced as soon as possible. But even a lesser fee will provide the Board with a large annual income, and the expenditure on building will not recur.

At its last meeting Mr. F. D. Acland admitted that the main problem before the Dental Board for some years would be that of students. If before the war the annual entry of about 250 students maintained a practising list of about 5000, how large an annual entry, he asked, would be required to maintain a practising list of 13,000, and how many more in order to raise that list to 16,000, the basis apparently agreed upon as desirable in the interests of public health? Mr. Acland remarked that the larger part of the funds of the Board being derived from those who had obtained registration by virtue of past practice, it was only fair that a reasonable proportion of the income should be devoted to their interests. The Dental Board have made a substantial beginning in subsidising dental study. Supplementary grants amounting to over £800 have been made to dental students who were in receipt of grants made by the Government after the war to enable them to qualify, and these grants having proved insufficient, a further sum of £700 has been set aside for the same purpose. Further, the treasurers of the Board have been authorised to make loans, under approved safeguards, to dental students not coming under the above heading, in order to enable them to qualify. Secondary schools in the United Kingdom have been approached with a view to the payment of fees for the dental education, and, in some cases, of maintenance grants for suitable persons desiring to enter the dental profession; and dental schools have been encouraged to enlarge their accommodation and teaching staff. It may be hoped that the Board will soon be in a position to arrange facilities for the simple and practical teaching of the principles of operative dentistry to the newly-registered men: many of them are pathetically anxious to learn and are under no illusions as to the present standard of their knowledge and skill. Money expended in this direction will reap a rich harvest in an improved standard of operative dentistry. It can hardly be doubted that the qualified dentist, accepting a situation which, however undesired, is now inevitable, will rise to the occasion and loyally undertake the task of helping to educate his unqualified brethren. These men now constitute a numerical majority, and the public at large will judge the dental profession by the standard of work which prevails among dentists as a whole. The instructional lectures already delivered in London have been well attended and appreciated. Over and above all this, considerable funds are likely to be available for dental research, and there is hardly a department of the healing art in which research is more needed or more likely to be attended by fruitful results. The appointment of Mr. W. H. Dolamore on the Dental Caries Research Committee may be mentioned to be warmly welcomed.

The Departmental Committee on the Dentists Act foresaw the social status of the dental profession to be intimately connected with its government, and everything depends on personal and collective adherence to a high ethical standard. It is believed by the dentists themselves that the overwhelming majority of the 12,762 dental practitioners on the Register will submit themselves voluntarily to the necessary discipline. It is to be hoped that the Board will enforce a stringent standard of conduct, inasmuch as many of those who have been admitted to the Register under the new Act may have carried on their practices by means of advertising and other non-ethical methods. Any continuance of such methods would reflect on the ethical standard of the dental profession as a whole. It would be manifestly unfair to the qualified dentist, who submitted to a striking dilution of his branch of the profession by unqualified men in the interests of the public, if his professional status should become lowered by the tolerance of unethical methods among a certain number of the newly registered. And it must be repeated that the public at large is unlikely to discriminate between the two classes which compose the official roll.

◆

THE FUNCTIONS OF THE LIVER.

What physiologist surveying our present knowledge of the liver can fail to be depressed by the mystery which still envelops the functions of this organ? Happily there are to-day a larger band than ever of enthusiastic workers striving to enlighten our ignorance on this subject. Evidence of this may be seen in the lecture on the Physiology of the Liver, by Sir Humphry Rolleston, which is published in the current number of the *St. Bartholomew's Hospital Reports*. The President of the Royal College of Physicians of London, in this lucid survey, emphasises the enormous functional reserve recently demonstrated by Mann and Magath, who have succeeded in removing large fractions of the liver in dogs without serious injury to the health of the animal. By the application of improved technique they have been able to remove the whole organ so as to produce the characteristic symptoms of hypoglycæmia—weakness, flaccidity, return of reflexes, muscular twitchings, and convulsions—from which condition the animal can be several times temporarily restored to health by the administration of glucose. This same reserve of physiological activity is demonstrated by the work of Rous and McMaster, who found that as little as one-twentieth of the biliary system sufficed to secure efficient secretion of the bile, with no occurrence of jaundice, an observation which, as Sir Humphry Rolleston points out, must throw doubt on the possibility of simple obstruction of one hepatic duct in man causing jaundice. The work of Meltzer on the reciprocal innervation of the gall-bladder and of Oddi's sphincter has found practical application in the non-surgical biliary drainage introduced by Lyon, although doubts as to the deductions of that worker have been raised by Einhorn, whilst Auster and Crohn dispute the actual findings of Meltzer. Still more controversial is the question of the origin and function of the constituents of the bile. As regards bilirubin, many authorities hold it to be purely an excretion, whereas C. M. Jones believes that from its precursors the liver can synthesise hæmoglobin. The general tendency of workers appears to be to consider bilirubin largely as a product of extra-hepatic origin, Van den Bergh and his followers claiming that two distinct forms of this compound may be recognised in pathological blood-sera. Nor is our knowledge concerning cholesterol in any way precise, neither its relation to disease, nor its origin and physiological uses being yet clearly defined. In these circumstances it is hardly surprising that the discussion, reported in our last issue, on the Value of Laboratory Tests in Diseases of the Liver, which took place at the Medical Society of London, should have disclosed an absence of agreement amongst laboratory workers, and considerable scepticism amongst clinicians. Prof. F. Langmead stated that he had rarely received from such laboratory tests information which was of value either for purposes of diagnosis, prognosis, or treatment, although he was careful to add his high opinion of the value of the chemical work as an aid to research. It is an interesting reflection to consider what might be the state of our knowledge concerning the liver and hepatic disease if hæmoglobin and its derivatives had chanced to be colourless substances. Would even catarrhal jaundice be now recognised as a clinical entity? Yet, when we remember the manifold important functions of the liver apart from bile secretion, it seems probable that the future has in store many important discoveries as to its pathology.

◆

THE PROBLEM OF HOOKWORM.

The results of what are probably the most comprehensive investigations ever undertaken on the important subject of hookworm infection have been appearing during the past two years in the *American Journal of Hygiene*. On some of the earlier reports we have already touched.[1] They embody the work carried out by a scientific commission emanating from the School of Hygiene and Public Health, Johns Hopkins University, Baltimore, with the coöperation of the International Health Board of the Rockefeller Foundation, and consisting of Prof. W. W. Cort, Dr. J. E. Ackert, and Mr. D. L. Augustine as scientific members, with the medical coöperation of Drs. G. C. and Florence K. Payne. Not a little has been heard of American methods of popular propaganda as adjuncts to actual medical treatment, and recently Prof. R. T. Leiper, of the London School of Tropical Medicine, has exhibited one of the cinematographic films used in this campaign, a film profound enough to arrest popular imagination, yet in vein sufficiently light to be amusing and therefore instructive even to children. Such methods, of which the "swat that fly" campaign is another happy example, can hardly fail, for the time being at least, to create a more intense and lasting impression on the popular mind than the reams of printed public health notices familiar to those of the past, and even the present, generation. Such campaigns can only successfully be conducted on business lines, and we have long had to admit that in the matter of advertisement American methods get home. The serious work of the American commission requires, however, no extraneous advertisement. The sober published reports speak for it in a convincing manner, and even to those who generally fail to appreciate the value or raison d'être of medical research, the results must come with some degree of illumination.

It has long been realised that medical treatment of hookworm infection in endemic areas is, in itself, a sheer waste of money, and for the same reason that statement is also true in the case of most other infectious diseases. Hookworm disease is one of these in which medical treatment is of secondary importance, and in which administrative preventive measures produce the only permanent results. One effort directed towards prevention is worth a hundred directed towards cure. We have had several ankylostoma commissions even in Europe, the most familiar of which, perhaps, are those which dealt with the St. Gothard tunnel outbreak and the endemics in the Westphalian coal-mines and the Cornish tin-mines. These commissions did their work well, but, although on paper it would appear to be a moderately easy matter to treat and cure hookworm infection, yet the Westphalian outbreak alone is computed to have cost Germany over a quarter of a million pounds. With the admitted efficiency of German disciplinary methods we may assume that the Westphalian results represented the highest degree of perfection attainable at the time. Unfortunately, hookworm campaigns in general have not to deal with intelligently disciplined people; in the West Indies and Southern American States the difficulty of the problem is greatly magnified. Until a few years ago the major part of hookworm experimentation and investigation had reference to conditions on the surface of the soil. The work of the American commission, however, has demonstrated conclusively that surface infection is only one phase in the free life of the hookworm, and that in actual fact the hookworm larvæ spend a considerable part of their life in the soil at various levels. This fact alone demonstrates the futility of purely surface disinfection, useful, no doubt, in some cases but entirely ineffective in the main. Vicarious local disinfection is, of course, of no more use in hookworm infection than it is in, say, typhoid fever, and to secure the universal adoption of local disinfection has proved beyond the power of even the most stringent sanitary authority in this country.

The destruction or the proper disposal of excrement, as in the modern water-carriage system, is an absolutely effective preventive of hookworm infection, but in countries where hookworms are prevalent such resources are lacking or inadequate, and even where present it is frequently an incredibly difficult matter to enforce their full and proper use. But the problem is much more than a matter of the mere deposition of fæcal material. Under suitable conditions it takes only a few days for the hookworm eggs to hatch, and at that point comes the real trouble, for the larvæ start to migrate. The phenomena asscciated with this migration are amongst the most interesting disclosed by the American workers, who have shown that the migration is not essentially or even to any great extent a surface one, but is, in actual fact, a more or less vertical one into the depths of the soil. Such a circumstance obviously renders the detection of soil infection a more complicated matter, for infected soils cannot invariably be detected by merely examining surface scrapings. Fortunately, a method, devised by BAERMANN in Java five years ago, has proved remarkably effective in ascertaining the presence of hookworm larvæ in soil samples, and has simplified work very considerably. This apparatus and its modifications are described in the second report, and all who may be practically interested should consult it. The third report disposes of the fallacy that hookworm larvæ live in a sheathed condition in the soil. The fourth and fifth reports refer to the part played by domesticated fowls and pigs in dispersing hookworm eggs and larvæ, and at the same time confirm the existence of a distinct species of hookworm in the pig (*Necator suillus*). The sixth and seventh reports consist of an interesting study of the effects of control measures in circumscribed localities. The eighth, ninth, and tenth reports deal with the life of the hookworm larvæ in the soil. The eleventh and fourteenth reports refer specifically to the phenomena of vertical migration, and reveal the fact that in certain circumstances, depending on the nature of the soil, hookworm larvæ may migrate from infected fæces buried as deep as three feet in the soil. It is thus evident that the mere superficial burying or covering over of excrement affords little, if any, protection against the migration and spread of hookworm. Such superficial procedure may, in fact, have quite the reverse effect, as has, indeed, been practically demonstrated by experimental work in Queensland. The investigations are proceeding and further valuable reports may be anticipated.

---

[1] The Lancet, 1922, i., 1057.

THE RUSSELL CASE.

THE Hon. J. H. Russell has obtained, after a prolonged second trial, a decree nisi of divorce from his wife, Christabel Hulme Russell. It is not necessary to refer to all the particulars of the unhappy married life of this young couple, published as they have been with a fullness of detail that has justly aroused much adverse criticism. One of few important facts not in dispute was the birth of a child during the marriage, the paternity of which, however, the husband denied. As to this a question was left to the jury by the judge at the end of his summing-up "was Mrs. Russell guilty of adultery with a man unknown, whereby she became the mother of a child born in October, 1921?" This was answered in the affirmative, but a co-respondent who had been named was dismissed from the case. The breach between husband and wife may have arisen out of their youth and lack of knowledge relating to the essential facts of matrimony, and out of the expressed desire of the wife to evade, at least temporarily, the ties of maternity. When, some time after conception had taken place, Mrs. Russell submitted herself to medical examination conditions were found consistent with the allegation that complete intercourse between husband and wife had not taken place. It was, of course, open to the jury to believe Mrs. Russell's story of her aversion from normal sexual intercourse, and that whatever evasion of it she practised with her husband had resulted in the conception of a child after similar acts with another man, or they may have regarded her account of her attitude with a measure of disbelief. In any event, the evidence given at the recent trial contains the lesson, for those who care to learn it, that the obligations of marriage and the natural impulses of man and woman are not to be trifled with or lightly evaded. It is stated that an appeal has been entered in which the result of the trial will be questioned, and the judge has pointed out that the exact status of the child remains yet to be determined by further proceedings.

Annotations.

"Ne quid nimis."

A GREAT PROSECTOR.

THE announcement of the death of Mr. William Pearson, formerly prosector to the Museum of the Royal College of Surgeons of England, will be received with deep regret by a wide circle of medical men. It is our national pride that the class which gives England her working men throws up numerous individuals who have the understanding of statesmen, the hands of artists, and the behaviour of natural gentlemen. William Pearson was one of these men. He enriched the Museum for which he worked for almost 58 years with preparations which are noted all the world over for their unique craftsmanship and felicity of design. He came to the scene of his life's labours in 1856—the last year of Sir Richard Owen's conservatorship. He was then a lad of 15. He served in turn under Quekett, Flower, Stewart, and Keith until 1914, when on account of failing health and at the age of 73 he retired to his home at Waddon, Surrey, where he died on March 15th, 82 years of age. He was the honest counsellor to four generations of conservators. He saw 33 presidents come and go, but from the time of John Hilton to that of Sir William Watson Cheyne every president recognised in William Pearson not only a faithful servant of the College but a valued personal friend. For over 50 years his was a familiar face in the examination rooms of the College, and many a nervous candidate has reason to remember the urbanity and tact with which he handled them during a trying ordeal.

With Pearson's death goes the last link which bound the present staff of the Museum with that of Hunter's time. As is well known, the staff of the Museum for ten years after Hunter's death was represented by one man—William Clift, who became first conservator. In 1804, when the Museum was transferred from Leicester-square to Lincoln's Inn Fields, William Clift engaged Edward Pearson as a museum porter. Edward died in 1857, having served the College for 53 years. His son, Thomas, was engaged as an attendant in 1837 and was pensioned in 1880 after 43 years of service. William Pearson, who has just died, was son of Thomas, and, as already said, began work in 1856 and retired on a liberal but fully earned pension in 1914, after almost 58 years of service. Thus three generations of Pearsons have given the College 153 years of service. William Pearson was buried in the Mitcham-road Cemetery, Croydon, on Monday, March 19th, his former colleagues at the College and Examination Hall being fully represented.

THE EFFECT OF QUININE ON THE ACUITY OF HEARING.

QUININE in certain doses is well known to produce well-marked effects on the auditory apparatus, including a degree of deafness and tinnitus. The question arises whether the tinnitus has any appreciable effect on the acuity of hearing at any and all pitches. The disadvantages of the watch-tick as a test for minimum audibility are obvious, nor is the tuning-fork free from error. A. G. Pohlman and F. W. Kranz[1] describe their method for determining minimum audibility as a function of pitch, pointing out, however, the extreme importance, in work on minimum audibility, of bearing in mind the variable factor of attention. It was found that a 25 gr. dose of quinine sulphate taken in 5 gr. gelatin capsules at hourly intervals does not materially influence the acuity of hearing. A 45 gr. dose, taken in 15 gr. doses one half-hour apart, produces in five hours pronounced tinnitus—defined as a subjective sound like locusts singing in the trees—a more marked sensation of fullness in the ears, and a pronounced decrease in acuity, particularly for high-pitched sounds (1000–1800). A total dose of 75 gr. taken in sub-divided doses within a few hours, also produces a pronounced decrease of acuity, appearing to affect the lower part of the scale (256–1000) more markedly than the upper (1000–1800). It would, however, be difficult to be sure of the amount of the drug absorbed. It was found that the amount of actual loss of acuity of hearing was not proportionate to the loudness of the tinnitus. After hearing returned to normal, the tinnitus continued for at least 24 hours. It is well known that tinnitus may be produced by exposure to loud sounds. A person was placed for three and a half hours with his head three feet in front of a telephone receiver which emitted an extremely loud note (1300), so loud that it could be heard outside the building. The tinnitus and sensation of fullness in the ears was as apparent as in the 40 gr. quinine test, and did not entirely disappear for 36 hours. The tinnitus so produced does not bear any definite pitch relation to the frequency of the sound causing the condition. The acuity of hearing was not impaired after the three and a half hours' exposure. Recovery of normal hearing after ingestion of quinine occurs in 24 to 36 hours. The toxic actions of quinine affect not only the auditory sense, but the entire nervous apparatus, so that definite readings with larger doses are not possible.

FINANCIAL RECONSTRUCTION FOR VOLUNTARY HOSPITALS.

Sir George Beatson, whose association with hospitals extends over a period of 50 years, for 32 of which he has been a member of the surgical staff of an important hospital with medical school attached, has set out his views on financial reconstruction in a little pamphlet [1] just issued. The hospital organisation adopted by the Scottish Red Cross during the war afforded valuable experience in the grouping of auxiliary hospitals of less pretentious build and equipment around a central hospital with full surgical service, so providing enhanced accommodation at relatively smaller outlay. Sir George Beatson finds nothing wrong with the management of individual hospitals: he is a convinced believer in the merits of the voluntary system, but he desires to have a reorganisation of this system with a definite policy and the coöperation of all parties concerned. The voluntary hospitals perform a widespread social service and carry on a great educational work that benefits all classes of society, but while nearly everyone is willing now to admit this the constant reiteration of monetary needs is, he fears, making the public indifferent to appeals. The present embarrassed financial position is due in the main to the fact that the voluntary hospitals are now doing work for which they were not established; they are meeting the needs, not merely of the necessitous sick poor, but of the lower middle and artizan classes. Any change in the financial system should allow for contributions from all classes of the community, should avoid the necessity for recurrent appeals, without opening the door for interference with the control of the hospital by any special body of contributors. Sir George Beatson's expedient for easing the financial situation is to divide hospital expenditure into two categories: (1) Expenditure for maintenance of hospital—to be met as hitherto; (2) expenditure on maintenance of patients—to be met by the patients themselves. Experience in the Glasgow Royal Infirmary shows that about two-thirds of the annual expenditure comes in the first and about one-third in the second category, and Sir George Beatson assumes that the same proportion will be found to prevail elsewhere. The bigger share of the burden would accordingly remain on the general public, the smaller share on those who use the hospitals. The cost of food in Glasgow would be met by a charge of 1*s.* 9*d.* per day per patient, while a flat rate of 10*s.* would suffice for drugs for each medical patient; surgical operation cases would be called upon to pay 2 guineas to meet the cost of anæsthetic and dressings. The average stay of a surgical case in hospital being 21 days a charge of £1 16*s.* 9*d.* would cover food, making a total of £3 18*s.* 9*d.*; a non-operative surgical case would be charged for the same period £2 17*s.* 9*d.* and a medical case £2 6*s.* 9*d.* A scheme of insurance for covering the cost of treatment to the patient should be arranged by the applicants themselves and not by the hospitals. The formation of "hospital treatment insurance societies," prepared to meet the maintenance charge for their members when in hospital, would, in Sir George Beatson's view, disarm any criticism raised against contributory schemes and provide an excellent basis for maintenance. There would still remain an income limit for admission, the hospital authorities would continue to be sole judges of the suitability of a case, and there would be no ground for medical men claiming remuneration for services rendered in hospitals inasmuch as the hospitals would themselves be receiving no payment for treatment. Should the hospital admit cases from Poor-law or pensions authorities, maintenance fees only would be charged, thus placing these patients on the same footing as other admissions. There is, Sir George Beatson feels, a limit to the patience and generosity of subscribers, and unless the voluntary principle is at once safeguarded in some such way as he suggests, he fears that the principle may be lost for good and all.

ACQUIRED STRICTURE OF THE MALE URETER.

Dr. Robert H. Herbst and Dr. Alvin Thompson,[1] of Chicago, remark that most of the literature on stricture of the ureter deals chiefly with strictures which are congenital, tuberculous, accompanying or following stone, or due to focal infection, whereas the possibility of ureteral stricture due to infected seminal vesicles, to which they drew attention in 1918, has been mentioned by only a few writers. Obstructions of the ureter due to this cause often pass unrecognised, owing to the symptoms being frequently masked by those of the genital tract, and they are not discovered until the patient has undergone a careful cystoscopic and rontgenological examination. Stricture of the ureter is usually found in early and middle adult life, which is the period when infection of the prostate gland and seminal vesicles is most common. The organisms which are the primary ætiological factors in the occlusion are the bacteria which commonly cause infection in the genital tract—viz., the gonococcus, *B. coli*, &c. Pathologically there are three degrees of obstruction: (1) Congestion, in which there is swelling often accompanied by œdema and usually associated with acute prostatitis and seminal vesiculitis. (2) Inflammatory type, in which there is infiltration of the ureteral wall, which may exist for some time without leading to connective-tissue proliferation. (3) Fibrous stricture, which follows the inflammatory type, and is mainly caused by the chlorides in the urine. The early symptoms are often those found in prostatitis and seminal vesiculitis, especially in the inflammatory stage before marked renal obstruction has developed. Micturition is frequent and imperative with pain at the end of the act, and the urine is filled with pus and shreds. Pain, which is probably the commonest symptom, may vary from a dull ache in the lower pelvis, which may or may not radiate up along the course of the ureter, to a severe renal colic. The temperature, which is continuous or intermittent, indicates infection of the renal pelvis. Blood may be found in the urine as an early sign, and may come from the ureteral wall in the inflammatory stage, but hæmaturia does not usually occur till later, when destructive changes have occurred in the kidney. A uretero-pyelogram is the most valuable and reliable method of diagnosis, as it not only shows the site of the stricture, but also reveals the extent and degree of ureteral and pelvic dilatation. Absence or impairment of peristalsis in the mural portion of the ureter on cystoscopic examination is of diagnostic value, as it indicates a thickening and rigidity of the extreme lower end of the ureter and surrounding bladder wall. In the early stage treatment of the infected vesicles and prostate will sometimes be followed by subsidence of the occlusion in the ureter, and the renal symptoms may entirely disappear after routine massage, vasotomy, or vesiculotomy. In the indurated type gradual dilatation with bougies is indicated. In cases which fail to respond to dilatation, and in which the stricture is limited to the mural portion of the ureter, an incision should be made by a hook-shaped knife introduced through an operating cystoscope or through the opened bladder. Strictures extending beyond the mural portion of the ureter which do not respond to dilatation should be excised. In long-standing cases, complicated by hydro- or pyonephrosis, nephrectomy is indicated.

[1] Journal of Urology, February, 1923.

ARE THE VARIOUS TYPES OF TUBERCLE BACILLUS STABLE?

IN his big work on the Causes of Tuberculosis, published in 1917, Dr. Louis Cobbett came to the conclusion that the main types of tubercle bacilli—the human, bovine, and avian—have doubtless descended from a common ancestral type, but have now become fixed and stable. In other words, they do not tend to change from one type to another even when the conditions for such a change are made as favourable as possible. He qualified this opinion with the reservation that this stability might not prove absolute if certain new conditions were to be prolonged indefinitely. A recent report[1] by Prof. A. Eber, of Leipzig, and Prof. L. Lange, of Berlin, shows that the final solution of this problem has not yet been found. Early in 1913 an elaborate scheme for solving this problem was organised as a sequel to a conflict of evidence arising in connexion with earlier investigations. At the Veterinary Institute in Leipzig Prof. Eber had demonstrated to his own satisfaction that, by animal passage, the human can be converted into the bovine type. A group of Berlin investigators who repeated his tests came to the opposite conclusion. This conflict of evidence led to the establishment of a scheme of combined research, the Leipzig and Berlin workers arranging to pursue the same lines of research with the same material and technique. The outbreak of the war seriously crippled the work in Berlin, but in Leipzig it was continued with waning vigour till the autumn of 1919. Some idea will be given of the magnitude of the research by a recapitulation of the following data. In Berlin, 21 cattle, 166 rabbits, and about 750 guinea-pigs were used, and 45 pure cultures of tubercle bacilli were grown. In Leipzig, 48 cattle, 256 rabbits, and 1031 guinea-pigs were used, and 114 pure cultures were grown. The original strains of tubercle bacillus were obtained from eight cases of pulmonary tuberculosis in man, and from a pure culture of the Schröder-Mietzsch strain of bacillus. The report, which occupies 110 pages, gives a full account of the technique and of the numerous precautions taken to prevent sources of error from confusing the issues. After Prof. Eber and Prof. Lange have given separate accounts of the investigations conducted in Leipzig and Berlin respectively, they publish a combined statement in which they agree that in none of the eight cases of human pulmonary tuberculosis did they succeed in completely converting the human to the bovine type. But certain tubercle bacilli, passed through a guinea-pig and then through cattle, did show changes, suggesting that a type had been evolved which was somewhere between the human and the bovine types. By their delayed and granular growth in pure culture on glycerine bouillon, and by their increased virulence to cattle and very marked virulence to rabbits, these bacilli appeared to have acquired properties not possessed by their immediate ancestors. In another instance, the pure culture of the Schröder-Mietzsch strain, originally of the human type and virulent to rabbits but not to cattle, became increasingly virulent to cattle on repeated passage. In conclusion, it is admitted that the problem of conversion of one type to the other by animal passage is not yet solved. So far the report is unsatisfactory. But in the course of their work Prof. Eber and Prof. Lange acquired a fund of knowledge of experimental infection with the tubercle bacillus, and this knowledge, much of which is communicated in the present report, should be of great value to workers undertaking similar research in the future.

INTRATHECAL INJECTIONS OF SODIUM BROMIDE.

IN 1913 the first report was published on the use of a solution of sodium bromide intrathecally for delirium tremens. Dr. H. Lippmann of Berlin[1] now reports on its application in cases of tabes, suffering with shooting pains in the lower limbs, and in cases of spastic paralysis. In order to determine the effect of the solution on the meninges he started with weak concentrations (1 per cent.) and gradually increased the strength, the reaction of the meninges being ascertained by an examination of the cerebro-spinal fluid, with special attention focused on the number of cells and the presence of albumin. Out of 40 injections, in five only was there any subjective disturbance or rise of temperature, and the degree of reaction did not seem to be dependent on the strength or quantity of the solution used. For example, 20 c.cm. of a 5 per cent. solution were injected in one case of tabes without producing any objective or subjective symptoms, whereas another case who received 18 c.cm. of a 3 per cent. solution, developed a temperature of 38° C. This case, however, had previously had a temperature of 37·8° C. on several occasions, and had suffered from renal sclerosis, uræmia, vomiting, and delirium. She reacted to the injection with delirium and vomiting, and the number of cells in the cerebro-spinal fluid was found to be 4600, 24 hours after the injection. In spite of this, in a further 24 hours the patient was completely relieved of her symptoms. One case had a rigor, and the temperature shot up to 40° C. after the injection, but it returned to normal in a few hours. A third case was a man, aged 67, suffering from severe bronchitis, coronary sclerosis, and a large cerebellar cyst, causing the spasticity for which treatment was undertaken. After the injection the temperature rose to 38·2° C. and cervical rigidity became marked. The cerebro-spinal fluid contained 6000 polynuclear cells, which in 24 hours decreased to 120. The man died four days after the injection, probably from angina pectoris. The rapid diminution of the cells indicated that the meningeal irritation was not the direct cause of death. Two other cases had a slight rise of temperature which rapidly sank to normal, but they had both previously had cystitis with a subfebrile temperature. In the majority of cases examination of the cerebro-spinal fluid showed about 100 cells following injection, although in some of these a similar number had been found previous to treatment. In some whose cell count was increased before injection, the number subsequently diminished to 3–6 cells. The albumin in most cases was slightly increased temporarily. Microscopical examination of the meninges in the patient who died showed how little inflammatory change had been produced by the solution. Dr. Lippmann states that from his experience in most individuals no reaction is produced by sodium bromide, but in a few cases a slight reaction occurs which disappears clinically within a few hours. He treated five cases of tabes with shooting pains in the legs, of whom two were greatly improved, one was slightly benefited, the fourth was refractory, and the fifth died of coronary sclerosis. Three cases of spasticity of the lower limbs were treated with marked improvement in all. For a detailed report of the cases we refer our readers to the original. An attempt to relieve pain caused by secondary carcinomatous deposits in the spine was unsuccessful. In the tabetic cases a 1 per cent. solution was used, in the spastic patients a 1·6 per cent. solution, which is isotonic with the body fluids; 10 c.cm. of the cerebro-spinal fluid was allowed to run out and the same quantity of the sodium bromide solution was introduced. The injections were given at intervals of 14 days or more according to the clinical manifestations. In the tabetic cases not more than three injections were given, but in the cases of spasticity they were repeated more often, up to eight times in one case. The injection of sodium bromide can also be used for the X ray diagnosis of the level of spinal tumours.

---

[1] Deutsche medizinische Wochenschrift, Feb. 23rd, 1923.

How the bromide acts therapeutically is not clear. It has no anæsthetic action on peripheral nerves, as can be demonstrated by subcutaneous injection, and that it does not remain long in the spinal canal is shown by the fact that 24 hours after injection less than a thousandth part could be recovered. Whether the action is chemical or bio-mechanical following the reaction of the meninges must remain unsolved until further observations reveal the nature of the process.

COMMUNISM AS AN INCURABLE MALADY.

It is not from the pronouncements of a reactionary school or institution that we derive the above definition. It comes from a doctor in Russia, himself in the service of the Bolshevists. It is the text of a lecture delivered by Dr. Salkind, and published in the *Izvestia*, on the psychology of Russian communism and the mental diseases it provokes. According to Dr. Salkind, the Russian communist is obsessed by one single idea: with a sort of religious fanaticism his faith is fixed on one single belief, that the only road to the world's salvation is by a "world revolution." Lenin has proclaimed, more than once, that nothing can be done in Russia alone, but that the revolution must be universal, and this is the Russian communist's view. But now that there has been considerable delay in realising a world revolution, a state of tension has resulted among the communists, and persons whose constitutions have suffered from years of war and insufficient food can hardly bear the stress. Therefore various forms of mental disease have increased. The most usual symptom is the obliteration of the feelings of love and tenderness which the subjects formerly experienced: there is no room for such emotions. And now instead of the revolution spreading, such approach to real communism as was at first established in Russia is being gradually encroached upon. Trade, private enterprise, and what is known as capitalism are returning to Russia. And this is an aggravation of the true communist's malady. He was ready to forsake all for the cause; he had devoted heart and soul to abolish "bourgeois institutions," and now even Lenin, or whoever is at the helm in Lenin's sickness, allows them to return. On a constitution debilitated by long suffering, on a mind inspired by an ardent and sincere faith, the shock and disappointment may well have had disastrous results. Therefore Dr. Salkind proposes that the subject of communism, as constituting an "incurable malady," should be discussed at the next congress of the Bolshevist party. This is probably the first time in history that a political party, actually in office and governing the country, has been called upon by a medical authority so to modify its policy as to reduce the prevalence of mental diseases.

ENDEMIC GOITRE IN TASMANIA.

The annual report for the year 1921–22 of the Department of Public Health of Tasmania gives evidence of a high standard of public health work. The chief medical officer, Dr. E. S. Morris, evidently has to combat the same wave of parsimony in public health matters which is impeding similar work in this country; and he urges with force that in these days of "increasing nationalisation in answer to the popular cry for State control as the panacea for all ills," public health offers an untrodden and legitimate domain for the statesman who will cultivate it. The most interesting section of the report comprises an investigation into goitre which is endemic in many parts of Tasmania. This disease was made voluntarily notifiable for 12 months, and although the returns may possibly not give an accurate index of local prevalence, the 644 cases which were thus notified throw considerable light on the subject. A somewhat elaborate questionnaire was issued, and from the returns the following information is culled. The disease prevails especially along certain river valleys, and especially in the southern half of the island, although no climatic or geological conditions emerged which could be thought of as accounting for this. Of the notifications, female cases were eight times as numerous as male cases (575 female to 69 male); and the largest number of cases notified was at ages 20–45. It is noteworthy that of 2581 school-children examined in schools in the southern portion of the State, 5–8 per cent. showed simple parenchymatous goitre. It is proposed to make the results of the inquiry the subject of further analysis; and in this connexion a comparison with American statistics in the great central belt in which goitre prevails would be interesting, as would also observations on the results of administration of iodine to school-children.

The House and Library of the Royal Society of Medicine will be closed from Thursday, March 29th, to Tuesday, April 3rd, both days inclusive.

Sir Frederick Mott retires on March 31st from his post of pathologist to the London County Mental Hospitals after a service of 27 years. He continues to assist the Maudsley Hospital in an advisory capacity.

To commemorate the 150th anniversary of the Medical Society of London, founded by Lettsom in 1773, a dinner will be held at the Hyde Park Hotel, on May 15th, Lord Dawson presiding. The Prince of Wales will be the principal guest, and a gathering widely representative of the medical profession is expected. The Medical Society of London is the oldest medical society in England.

Royal Northern Hospital, Holloway, London. A neurological section of the out-patient department is being opened on Friday, April 20th, and a session will be held weekly at 1 P.M. The new department is being inaugurated to cope with the large number of nerve cases applying for treatment, and an additional out-patient officer is being appointed. Forty-two separate sessions are now held in the out-patient department every week, and the attendances exceed 180,000 per annum.

Dangerous Drugs Regulations.—The Home Secretary gives notice of amending regulations under the Dangerous Drugs Act, 1920, to come into force forthwith. The chief alteration effected is that doctors, dentists, or veterinary surgeons, when giving prescriptions for dangerous drugs are no longer required to sign the prescription with their Christian names in full. Instead it is provided that the prescriber shall sign with his usual signature. On the other hand, a chemist shall only dispense a prescription for the drugs, either (*a*) if he is acquainted with the prescriber's signature, and has no reason to doubt the genuineness of the prescription, or (*b*) if he has taken reasonably sufficient steps to satisfy himself that the prescription is genuine. Copies of the amending regulations may be obtained from H.M. Stationery Office.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XII.—TREATMENT OF OBLIQUE INGUINAL HERNIA IN ADULTS.

Palliative Treatment: Trusses.

Not all patients submit to operation. Blank refusal, knowledge of recurrences, old age, possession of a recurrence, systemic disease contra-indicating operation; these are all circumstances calling for non-operative treatment—i.e., truss and care of the alimentary tract functions. Where reduction cannot be effected at once it may be possible after rest in bed and aperients. Measuring, fitting, application, supervision of the wearing of a truss, as far as possible, should have the personal attention of the medical attendant, and should not be left to the truss maker, as is not uncommonly done. Special pattern trusses are rarely required. Measurement for a truss should be taken with the patient lying down; the tape should be drawn tight round the body midway between anterior superior spine and top of great trochanter, passing down and meeting at the symphysis; side and character of hernia should be stated with the measurement. The pad must be nearly flat, must cover the whole canal, and at its broader end overlap the edges of the hernial opening. While the spring is the chief factor in holding back the hernia, the understrap is of value in preventing the pad riding up, and should always be worn. I have often seen patients without it. The tension of the spring should be adjusted on the patient and the pad adapted; the efficiency of the truss can be tested by movements, coughing and straining, and the patient must be instructed in its management. The truss is best always worn, and therefore a second—bathing pattern—is useful. Sometimes the patient has also to wear an abdominal belt, or a thigh-piece, or both, and these can be incorporated with the truss.

Hardly any operation is more frequently performed than that for inguinal hernia. It is done by operators of very varying experience, skill, and anatomical knowledge, whereas a high degree of all these is necessary. While there is little probability of danger, there is more of damage. "Recurrences" are frequent, not so much from sepsis, for this operators have learnt to avoid, but from imperfect technique, and recurrences are more frequent from relatively inexperienced hands. Before the operation is undertaken alone, repeated guidance in its performance on the living body with the assistance of an experienced operator is essential to all practitioners. Moreover, the different steps of the operation performed should be clearly appreciated.

The Operation.

A truss cannot anatomically cure a hernia, so that operation is advisable in all healthy adults. A "bubonocele"—i.e., a hernia which has not entered the scrotum—is the class of hernia for which operation at the present time is most frequently performed, and it is this operation that should be mastered by those who are only occasionally called upon to do their own surgery.

The genitalia, inguinal regions, lower abdomen, and upper thighs should be completely shaved and prepared, and the foreskin cleaned underneath. The patient should pass urine immediately before operation. Anæsthesia may be by "open ether" preceded by morphia and atropine injection. In fat patients the pelvis should be raised on a padded block. The incision should be about five inches long, reaching from one inch within the anterior superior spine to the pubic spine over the line of the canal, bisecting the interspace felt between external ring pillars; subcutaneous tissues are divided; superficial epigastric, external pudic and other vessels are seen, clipped before dividing, divided and tied. The surface of the external oblique, the ring pillars, and the cord coverings between the pillars are cleanly exposed. From the bifurcation of the pillars the external oblique fascia is divided outwards in the canal line for about 3 inches, the fascial flaps turned back, and the scanty intercolumnar fascia divided. The well-defined cremasteric fascia with its scattered muscular bands and the internal oblique are next divided; the latter for about $1\frac{1}{2}$ inches between forceps—which are removed later—because it bleeds. Finally, the thin transversalis fascia and its continuation on the cord, the infundibuliform fascia are divided, and on separating the overlying structures the sac is seen and identified by its pearly-white colour and sharp convex edge. Now the coverings are cleanly peeled off the sac (the sac may be opened and the finger put inside to assist in this), wiping with a piece of moist gauze. If necessary the vas can be identified; preferably the cord structures are not disturbed. The sac is separated to and just beyond where its peritoneum spreads out into the parietal peritoneum. Here behind and internal to the sac the pulsations of the deep epigastric artery can be identified. The sac is freely opened, its contents, if any, reduced, and it is removed. The division passes through the spreading out peritoneum, and is deeper than any circular white ring on the interior of the sac. Peritoneal closure is done either by a transfixing ligature, the ends of which are left long, passed outwards under the internal oblique and transversalis, and tied superficially to these muscles; or, by grasping the peritoneal edge with pairs of forceps as the sac is cut off, then sewing the peritoneal wound up. *The whole sac must be removed.* The internal oblique and cremasteric fascia are sutured. The flaps of the external oblique fascia are held back and the muscle above the canal sutured to the deep aspect of Poupart's ligament. The external oblique is sutured. These last two rows leave just enough room below for the cord to come through, and the subcutaneous tissue is sutured. Catgut is used throughout and the sutures are continuous. Hæmostasis is complete and a perfectly dry wound left. The skin is closed with Michel's clips, the wound dabbed with iodine, and sealed with collodion and gauze. Taking hold of the scrotum, a pull is given on the testis to straighten out the cord before the patient leaves the table.

Any position most comfortable to the patient is allowed in bed. The clips are taken out on the fourth day after operation and the wound resealed. The patient gets up in a week and—if in an institution—leaves in 12 to 14 days. Heavy muscular work is not commenced until at least six weeks after the operation. The patient is instructed to keep the bowels open regularly.

Comments on the Operation.

It will be observed that the operation combines exposure of the sac to and beyond its deepest part with a minimum of dragging on surrounding structures; that to do this the internal oblique, which lies in front of the sac, is divided; that the cord is disturbed as little as possible; that, after removal of the whole sac, the divided structures are reunited as cut with the additional parietal safeguard produced by joining the muscles to the deep aspect of Poupart's ligament; that no special instruments and no special methods of stitching need be used. The operation is for an inguinal bubonocele with little or no parietal deformation. Such form the majority of inguinal hernia operations now, this contrasting with, say, 25 years ago, when these small herniæ were treated by trusses, the larger and scrotal herniæ with gross parietal deformation being operatedon, the operation requiring special methods, such as Bassini's. Such methods are still given undue prominence in text-books and works on operative surgery, and are often unnecessarily practised on small herniæ.

"Bassini" Type of Operation.

Where the hernia is large and scrotal, the parietes weakened sometimes to the extent of external and internal rings being opposite to one another so as to form one large hole, or a direct hernia is present in addition to the indirect, then an operation of the Bassini type may be performed. The sac—of which the coverings are usually thick—is removed. The cord coverings are dissected away, and it is held aside by a loop of moist gauze; the external and internal oblique are sutured round it at the outer end of the wound, it is laid subcutaneously, and the parietal structures are sutured behind it down to the pubes. It is better to lay the cord subcutaneously than under the external oblique, as in the original Bassini operation. Sometimes the rectal sheath is drawn down, or a portion turned over as a flap, or a wire filigree inserted tucked in under the muscles and Poupart's ligament. Following interference with its contents the scrotum is strapped at the end of the operation.

Taxis.

It is safer not to attempt taxis in strangulated hernia. For those old, in ill-health, or refusing operation, it may be tried very gently, best under an anæsthetic. The risk of damage is less with mild symptoms and with recent strangulation. Taxis is permissible for irreducible hernia, and is more likely to succeed after preliminary rest in bed. If a right hernia, the left hand grasps and steadies the neck, and pushes the hernia down, while the right hand compresses the hernia up and out from its lowest part, so that the contents which come out last are reduced first, the sac contents returning progressively from the highest to the lowest, being felt to slip back through the relaxed fingers of the left hand. During these manœuvres the patient is lying down with head and shoulders raised and resting, and thighs flexed and supported. The patient, if not anæsthetised, is told not to lift the head to see what is happening.

Sundry Additional Points.

Retention of urine is less likely to occur if the patient is allowed to move freely in bed. After the ordinary operation there is no objection to his getting out of bed immediately on to the night stool.

Division of *nerves* should be avoided. The hypogastric branch of the ilio-hypogastric lies on the internal oblique, just above the canal. The ilio-inguinal goes in front of the cord through the external ring. The genital branch of the genito-crural supplies the cremaster.

Difficulty in Finding Sac.—The sac, if difficult to find, should be sought for at the outermost part of the wound. I have seen operators in trouble when searching towards the scrotal region.

The *bladder* sometimes is related to the inner part of the sac, most commonly in direct herniæ. Yellow granular fat indicates it. It may be loosened and pushed back, and a portion of sac may have to be left with it.

In a *sliding hernia* large bowel is fixed on the wall of the sac. It is reduced partly by separating, partly by putting back a portion of sac with it. On the right side the appendix, if seen, is removed.

Redundant omentum is removed by transfixing ligatures at different levels, so that there is not too bulky a stump to push back. The sac, if it contains the testis, is cut across transversely and a separate tunica vaginalis made.

A strangulated hernia is approached by the usual incisions; thus the contriction is most easily found. The operation includes a radical cure.

Irreducible, inflamed, obstructed herniæ are suitable for rest in bed and appropriate general and local treatment, but there should be no delay with icebag and opium when the hernia is strangulated.

Recurrence.[1]—The most usual cause of recurrence is leaving behind the deep part of the sac. In operating for recurrence this part is approached, as nearer the scrotum scar tissue may confuse.

Special Articles.

A NOTE ON CURRENT CASES OF ENCEPHALITIS IN GLASGOW.

BY A. K. CHALMERS, M.D. GLASG., D.P.H.,
MEDICAL OFFICER OF HEALTH, GLASGOW;
AND
A. S. M. MACGREGOR, M.D. GLASG., D.P.H.,
SENIOR ASSISTANT, PUBLIC HEALTH DEPARTMENT, GLASGOW.

TOWARDS the end of February it became apparent that an outbreak of encephalitis lethargica was occurring in the city of Glasgow, and that a number of the cases were of severe type and were showing uncommon clinical features. In these the irritative stage has tended to be more pronounced and more prolonged, and the febrile disturbance greater than in such sporadic cases as have been met with prior to and since 1920, the last period of undoubted prevalence in the city. In that year, 1920, many of the cases sickening in the spring and early summer were of somewhat severe type with fever, sudden onset, spasmodic or "choreiform" muscular agitation during the illness, tending to be followed by paresis or paralysis of groups of muscles.[1] We are now witnessing a recurrence of this type, in apparently greater number, and, in some instances, even more severe form.

Encephalitis lethargica was made notifiable in Glasgow in 1918, but it may be pointed out that evidence of its incidence based on notification is very unreliable, because, undoubtedly, the number (63) notified in 1920 did not reveal the extent of the epidemic, as many cases sickening during the year were only recognised and reported one, two, and even three years later, on account of typical sequelæ. It is probable that the notifications for this year will form a more accurate index of the prevalence of the disease, because of the experience gained in the epidemic of that year.

The Recent Outbreak.

The sudden appearance of cases of this sharper variety was observed and reported simultaneously by Dr. Leonard Findlay, Dr. Ivy McKenzie and others, at the same time as one or two patients of this type had been admitted to Belvidere and Ruchill Fever Hospitals, and the following account groups together the salient clinical features, so far as they are known, based on reports kindly furnished by Drs. Findlay and McKenzie, Drs. T. Archibald and W. M. Elliott of Belvidere and Ruchill Hospitals, and on investigations by the public health staff. Since the beginning of February, 38 cases of encephalitis lethargica have been notified or reported, one sickening in December, 1922, five in January, and the remainder in February of this year. The ages of the patients vary from 1½ to 56 years, 22 being over 15 years of age; 8 have died after illness lasting from 6 to 17 days. The cases are sporadic in incidence, distributed throughout the city, and quite unassociated with one another, in no case including more than one member of a family.

Clinical data are available in respect of 33 patients, a number of whom approximate to the classical description of this affection, where irritative symptoms are slight or absent, neuro-muscular disturbance confined to the ocular muscles, and drowsiness or lethargy a prominent feature. The majority, however, have a pronounced irritative stage, with excitement, delirium, and restlessness, especially during the night, sometimes requiring forcible control, while spasmodic, twitching, or choreiform movements of the limbs or of the whole body are a marked feature of most of the cases. These movements may be very violent. The onset is commonly that of an acute infection and the temperature varies from 100° to 102° F., occasionally higher, while hyperpyrexia may occur in fatal cases. In those cases where restlessness and twitching movements are prominent, they appear early in the illness, but there may be a preliminary period of a few days to a few weeks marked by headache, sleeplessness, neuralgic pains in the limbs, trunk, or face, giddiness, and occasional vomiting. Ophthalmoplegic symptoms, of which the chief is diplopia, are typical of the disease, but they may be transient or absent at the time of examination.

---

Cases with Acute Toxic Symptoms.

While this brief description may be regarded as fitting loosely the prevailing sharper type of case, others have occurred in which the acute toxic symptoms have been of excessive severity. As the presence of this acute variety is an important aspect of the outbreak the following example is quoted from Dr. McKenzie's description of a case under his care in the Eastern District Hospital, Glasgow.

Female aged 19. Onset of illness on Feb. 13th, with sleeplessness and restlessness; double vision developed on 15th, when patient became delirious. Next night she was delirious and highly fevered. On admission to hospital temperature was 103° F., and patient appeared very ill, very restless, constantly coming out of bed, and inclined to be resistive. Took her nourishment well, but did not sleep. Her attention could always be sustained, but she did not speak. She did not sleep even with sedatives till the night before she died, except for one hour. There was slight squint, no abnormality of pupils, reflexes normal, no paralysis. Patient had twitching of legs, arms, and body. There was no lethargy and no great psychomotor excitement. She died on the 23rd.

It will be noted that the patient died in the acute restless stage. An example of a prolonged irritative restless period may be quoted, also from notes furnished by Dr. McKenzie.

Married female aged 33. Onset of illness on night of Feb. 16th, with symptoms of chill with pain in right shoulder, restlessness, sleeplessness, and general twitching movements. Very ill on admission, with temperature 101° to 103° F. She had jerky tremulous movements not at all resembling chorea; more like clonus in the arms. There was also twitching of the face. She complained of headache, but had no squint or diplopia. Was very sleepless and restless, constantly trying to come out of bed, very delirious, but could always be recalled from delirium with ease. The movements have gradually become less, has slept under paraldehyde, and is no longer delirious. No evidence of lethargy.

Acute cases of this nature where lethargic symptoms are absent are exceptional in this series, but are quoted to show the severity and duration to which the irritative stage may reach. Another instance may be given of prolonged severity of motor and cerebral symptoms from a record kindly furnished by Dr. Findlay of a case under his care in the Royal Hospital for Sick Children.

A male aged 11. Admitted on Feb. 17th with history of severe headaches, slight fever, and disinclination for food of seven days' duration, with delirium on night before admission. On admission he had very severe headache, the reflexes were normal, and the pupils equal, reacting to light and on accommodation; on 20th child was restless and complained of pain in the flanks; left lateral nystagmus noted. Next day he was more restless, talking irrationally, very excited and attempting to get out of bed, but could understand what was said to him. On lumbar puncture the cerebro-spinal fluid was not under pressure, was clear, and contained an occasional lymphocyte. Lange reaction positive, of luetic type. Pandy negative. Two days later the choreiform movements became very marked, patient required sedatives, and even then had to be held down in bed. On 23rd he was unconscious, though he made attempts to answer questions, and remained so till death on 26th. The temperature varied between 100° and 102° F., with rapid pulse rising to 150 and 160 for four days before death.

Post-mortem.—Brain firm, with intense congestion of veins and small hæmorrhages into the basal ganglia. (Dr. A. S. Strachan, pathologist, Royal Hospital for Sick Children, Glasgow, has succeeded in transmitting the disease by intracerebral inoculation of the brain of this case through two generations of rabbits.)

Further Individual Cases.

The signs and symptoms referable to the involvement of the central nervous system in this affection are extremely varied, and it is difficult to give a concise description of its onset and progress. The former may be acute or gradual, and the latter brief or prolonged, with resulting exhaustion and mental impairment. The following descriptions of individual patients have been selected, in addition to the above, to illustrate the acuter types now prevailing.

Male, aged 13, under Dr. T. M. Campbell. Illness commenced six weeks previously with symptoms of influenza resembling a severe cold; at the same time he had pains in left arm and later also in left hip. A fortnight after onset boy became delirious and restless, never sleeping at all between 8 P.M. and 2 A.M., and never more than two hours at a stretch. For the next three weeks it was impossible to examine him properly on account of jerking and twitching movements. These were of a tremulous character, the body going into extreme states of flexion and extension with clonus-like movements of the limbs. These have now almost subsided. At no time, so far, has there been any drowsiness. At present he is emaciated, pale, and nervous, shivering when spoken to; pulse 120; pupils equal and moderately contracted; no diplopia; no stiffness of neck; tongue clean; heart and lungs normal. The boy has been able to read throughout his illness, though on one occasion he said that the lines of print ran into each other.

Female, aged 5, under Dr. Findlay, Royal Hospital for Sick Children, Glasgow, who has supplied the following notes. Admitted on Feb. 22nd with history of twitching of hands and feet of five days' duration; during the night child was very restless, tossing about the bed and pulling at the bed-clothes. She had slight fever, no vomiting, but bowels were very constipated. On admission the patient was semi-conscious, very restless, with constant choreiform movement of arms and legs, and twitching of face. Child could be roused and then answer questions, but speech was indistinct. No Kernig; slight nuchal rigidity; no paralysis, though face is expressionless and left upper eyelid is not raised so well as the right. Pupils equal and react to light and on accommodation. Lumbar puncture—fluid under slightly increased pressure; on centrifugalising only an occasional lymphocyte seen. Pandy—negative; Lange—positive. On the 24th child was quite unconscious, with marked choreiform movements of arms and at night was restless and could be roused. Nystagmus noted occasionally. Since then child has never been quite unconscious but drowsy, with occasional jerky movements of head and arms which become more marked during the night. Since Feb. 26th pupils react to light, but not on accommodation. No paralysis. Knee-jerks increased. Ophthalmoscopic examination: Pink discs, congested veins, and all fundus very red. Temperature since admission has been between 101–102·6° F. Pulse has varied between 140 and 170 per minute. Respirations have been very rapid, between 60 and 70, though no pulmonary lesion was detected.

Male, aged 8, reported by Dr. Elliott, Ruchill Hospital. Admitted on Feb. 16th. 1923, as a case of cerebro-spinal fever, with a history of having been ill since the 12th with fever, delirium, and latterly convulsions and retention of urine. On admission temperature was 100° F. The child was semi-conscious and could not easily be roused. There were no ocular symptoms and no signs of meningeal irritation. On lumbar puncture some practically clear fluid under pressure was withdrawn. An increased cell count of 30 per c.mm. was found. No clot on standing and no organisms of any kind were found. Both blood and cerebrospinal fluid gave negative Wassermann reactions. The day after admission the patient's mental condition improved very considerably, and he seemed quite bright. During the night of the 18th, however, the patient again became delirious, and in the morning mental confusion was present again. The urine showed a considerable amount of albumin. The temperature at this time was not elevated, it having fallen after admission. The patient remained, however, in much the same condition, twitching movements began to appear generally, and the pupils became contracted. The drowsiness appeared to pass off, and wakefulness took its place, and hypnotics failed to procure satisfactory sleep. The urine, which was examined on the 21st, appeared perfectly normal. The albumin had practically disappeared, and there were no abnormal substances such as acetone, sugar, or diacetic acid. Lumbar puncture was done again and no change noted in the fluid. The child's general condition became worse and he died on the 22nd. Post-mortem examination was made, but beyond intense congestion of the brain no definite macroscopical change was noted. (Histological report is not yet available.)

The following case is an example of gradual onset, ingravescent in type.

Female, aged 24, under Dr. Campbell, reported by Dr. R. S. Fullarton. Early in February patient, while feeling quite well, began to complain of not sleeping, and on Feb. 12th she had no sleep all night on account, she thought, of cramps in her stomach. She then visited Dr. Campbell complaining that she had had no sleep for a week. Dr. Campbell noticed her nervous manner and way of jerking her hands, now to her face, and now to different parts of her dress while she was speaking to him. On the night of the 13th she suffered from headache and sleeplessness, sleeping only two or three hours, and during the next three days she was much better and slept well at night. On the 16th and 17th she complained much of pain in the small of her back. At the same time she complained of "seeing double," but did not appear to be fevered. On Feb. 19th she was so sleepless as to require a sedative. Since then she has been somewhat better, but complaining of pains from time to time, and sleeping fairly well, but with no marked drowsiness. She has taken food well, the bowels have moved regularly, and there has been no delirium, but she talked in rather a wandering fashion immediately after waking from sleep. She has been able to get up each day to wash and have her bed made. On the 28th she seemed fevered, was disinclined for food, and exceptionally drowsy. On the 29th, when visited, she was very drowsy, spoke thickly when roused, had a temperature of 103° F., and pulse of 120. The tongue was dry; pupils equal and moderately contracted, no squint, and no stiffness of the neck.

The following case reported by Dr. Archibald, Belvidere Fever Hospital, and Dr. Fullarton, is probably as typical as any in the present outbreak.

Female aged 8. On Feb. 4th she complained of noises in her ears; on the 7th the eyes were congested and looked as if "she were taking measles." On the 8th patient's mother noticed that her legs were twitching and could feel the "jerks" of the thigh muscles. At night she had hallucinations and was very restless and "delirious," also complaining of pains in the calves of the legs. Admitted to Belvidere Hospital on the same day; on observation there the patient's illness fell into stages, the first marked by a period of delirium, restlessness (child getting out of bed), with lethargy, mental confusion, and choreiform movements first of the left side of the body, then of both sides; during this time the temperature was rising to 101–102° F. This period lasted for about six days from its onset. The next stage was one of constant drowsiness, lessening of choreiform movements, absence of excitement, and dazed facies lasting about a week, during which the temperature, at first sustained, began to remit. This was followed by a period during which the child showed morning brightness and evening drowsiness, absence of choreiform movements; the temperature was intermittent with evening rises to 100–101°. This lasted for about ten days, after which the temperature became normal and the child apparently well.

Symptoms Frequently but not Invariably Noted.

While the cases just described suffice to indicate the main features of the symptomatology, it should be pointed out that the cases do not readily fall into definite clinical types. Particular signs or symptoms may be absent or variously combined in different patients, with great variation in their duration and intensity. Among these the following are selected for mention, though they are by no means always present in individual cases of the severer types of illness.

1. *Symptoms of Onset.*—Initial complaint may be rheumatism or neuralgic pains in a limb, the shoulder, neck, face or abdomen, trifling or severe. Headache is common and vomiting occasional. Sleeplessness is a very prominent and early symptom. One or two have commenced with "influenza" or sore throat.

2. *Fever.*—In the acuter cases there may be fever from the beginning, continuous at first and later intermittent. In a few cases, usually fatal, there may be hyperpyrexia. Many patients, however, although showing much motor disturbance and delirium, may have little fever.

3. *Delirium and Restlessness.*—This may be extreme requiring forcible control. A feature of the delirium is that the patient can be roused and can answer questions sensibly enough, though there may be some mental confusion. Restlessness may be a continuous feature, or may alternate with drowsiness. When present, it occurs, or is worse, during the night.

4. *Involuntary Muscular Movements.*—These are variously described as twitching, spasmodic, choreiform, involving the feet, the limbs, or the whole body. In a severe case the body may be jerked from flexion to extension and vice versa, and the patient may have to be held in bed. Twitching has been definitely present in 18 cases in the present series. It may, however, be so slight as to be overlooked unless watched for. In milder cases it is not unlike the spasmodic contractions of tic. Spasticity is associated with its presence.

5. *Insomnia.*—This is an almost constant feature, sleeplessness being an early and noticeable symptom in most cases. It may precede onset of twitching by a few days.

6. *Lethargy.*—This may be present early in the case or later, succeeding the irritative stage. It may be noted that in a few of the patients it was not a prominent feature, but the great majority had this symptom in greater or less degree. The facies may assume a dull mask-like expression.

7. *Ocular Phenomena.*—Diplopia is the most frequent of these, and may be persistent or transient; ptosis may be present on one or both sides, and in one or two instances nystagmus has been observed. The appearance and reaction of the pupils vary considerably.

Table showing Admissions of Cases of Encephalitis Lethargica to Belvidere and Ruchill Fever Hospitals, Glasgow, between 1918 and 1922.

—	1918	1919	1920	1921	1922
First quarter ..	—	6	6	2	1
Second quarter ..	4	3	22	5	4
Third quarter ..	3	1	3	1	—
Fourth quarter ..	—	11	3	4	—

From the table given above, which represents admissions to the fever hospitals during five years from 1918 to 1922, it will be seen that there was a small peak of incidence during the fourth quarter of 1919, and again (more marked) during the second quarter of 1920, and that since then the incidence has been slight. This table does not, of course, give the true figures for these years, as many cases were treated in the various general hospitals in the city, especially during 1920, the year when the affection was last prevalent in the city.

THE GENERAL MEDICAL COUNCIL.

THE Executive Committee of the Council met on Feb. 26th, and among the items of business transacted were the following:—

Restorations to the Register.

The Registrar reported that—the prescribed conditions having been duly fulfilled in each case—the names of the undermentioned persons had been restored to the Medical Register, from which they had been erased in conformity with the provisions of Section XIV. of the Medical Act, 1858:—

William C. Ambrose, Thomas E. Amyot, Joseph L. Brown, Francis Byrne, William S. Carpenter, Ando Huan Chu, Claude T. Darwent, David E. S. Davies, Hugh J. Dickey, Charles W. Dixon, Thomas P. Dowley, Thomas J. Duane, Charles E. Etheridge, Thomas Evans, Aubrey G. C. Findlay, Reginald W. Fisher, John L. Goldstein, Thomas Gregory, Richard J. Harley, Daniel J. Hickey, Thomas W. Kelly, William R. Kilgour, George H. Patterson, William H. Pearse, Huntly N. Pelly, Stanley V. P. Pill, Hugh T. Prince, George B. Proctor, Thomas M. Robertson, William G. Robertson, John J. Savage, Harold H. Scott, Alexander Silberman, Arthur E. Thorp.

Medical Legislation in Saskatchewan.

The Committee considered a communication received in January from the Colonial Office transmitting copies of two Medical Acts—the Medical Profession Act, which became a revised statute in 1909 (now Chapter 135 of 1920), and the Amending Act, 1921–22, Chapter 59, which together comprise the complete law on the subject in the Province of Saskatchewan. The principal Act had not previously appeared upon the minutes of the General Medical Council. A resolution was passed by the Committee, thanking the Secretary of State for the Colonies for transmitting the copies of these Acts, and recording the Committee's satisfaction on observing the provisions therein contained for the prevention of unqualified practice. Among the provisions thus mentioned, under the sectional heading "Offences, Penalties, and Prosecutions," appears the following :—

> *Penalty for Practice.*—No person unregistered or under suspension under this Act shall practise medicine, surgery, or midwifery for hire, gain, or hope of reward, and if any person not registered or under suspension as aforesaid pursuant to this Act for hire, gain, or hope of reward practises or professes to practise or advertises to give advice in medicine, surgery, or midwifery, or who shall furnish medicine or treat any disease or ailment by medicine, drugs or any form of treatment, influence or appliance for hire, gain, or hope of reward shall be guilty of an offence and upon summary conviction thereof be liable to a penalty not exceeding $100.

Application for Registration in the Colonial List.

The Committee considered the case of Alexandre Achpise, a native of Poland, who possessed the degree of M.D. Paris and the Licence of the College of Physicians and Surgeons of the Province of Quebec, and had applied for registration in the Colonial List in virtue of the latter. The Province of Quebec differs from the other provinces of Canada, as the Provincial Licence of the College alone has never been recognised, but only the degrees of the Provincial Universities, on whose Board of Examiners the College are represented.

The Committee resolved as follows :—

> That the attention of the College of Physicians and Surgeons be called to the fact that they have never hitherto applied to the Medical Council for the recognition of their licence obtained after examination in medicine, surgery, and midwifery by the College, in the same way as application had been made for the recognition of the degrees of the provincial universities obtained in accordance with the regulations of the College ; and that if they were to do so the Council could take the matter into consideration at their May session, and that Dr. Achpise's case could be considered thereafter.

Public Health Resolutions and the R.A.M.C.

The Committee considered a communication received from the Presidents of the English Royal Colleges of Physicians and Surgeons, who submitted, on behalf of the Royal Colleges, that the new regulations for public health diplomas require modification ; the communication was referred to the Public Health Committee for consideration and report to the Council. In the text of this communication it was explained that considerable comment has been made concerning the hardship which the new regulations impose on medical practitioners generally and on Colonial, I.M.S., and R.A.M.C. officers in particular. Attention was called to points which may be summarised as follows :—

1. In the communication sent by the Royal Colleges to the Council in 1921, when the draft rules and resolutions were under consideration, it was assumed that instruction under the proposed new conditions might be taken under more than one medical officer of health, provided each period is certified by the officer under whom the study is taken.
2. In the rules as adopted all instruction has to be provided by one medical officer of health, and this requirement limits the number of medical officers of health in this country under whom the instruction can be taken, and practically precludes instruction under a medical officer of health in India or the Colonies. Some provision ought to be made to meet this difficulty ; for instance, a candidate who had attended for six months under a medical officer of health of a large area in India or a Colony might well be required to supplement this attendance by a short course of two months under a medical officer of health in this country for the various special services.
3. Officers in the R.A.M.C. were formerly allowed to take their instruction in the duties of a medical officer of health under a sanitary staff officer having charge of an army corps, district, command, or division, which is no longer permitted. An officer in the R.A.M.C. might well be allowed to take his instruction as before, with the proviso that he must attend for two months under a medical officer of health who is able to provide the special services.
4. Another question of general interest to candidates is the condition laid down that, whilst the curriculum extends over one year, a candidate shall not be allowed to take the second part of the examination until two years after his qualification. The Royal Colleges raised no objection to this condition when put forward in the original draft recommendations, but it has since been realised that the imposition of a waiting period of a year over and above the year of special study is a distinct hardship to (*a*) candidates who intend to devote themselves to special public health work but have not the necessary financial resources to maintain themselves for two years after completing their expensive medical curriculum ; (*b*) doctors who desire to practise abroad or in the Colonies ; (*c*) members of the Colonial Medical Services.

Erasure from New South Wales Register.

A communication from the New South Wales Medical Board was read, reporting that Frederick Sobieski Wladimir Zlotkowski had been found guilty of infamous conduct in a professional respect, and that his name had been removed from the Register of the State. This practitioner had never been registered in the United Kingdom, and appeared to hold the qualification of M.B.U. Sydney, 1896.

Correction of Register.

The Registrar reported that the systematic correction of the Register had been continued, and that circulars of inquiry were sent last year to all practitioners from the letters A to G. As a result of this revision and individual inquiries made during the year the names of 310 practitioners had had to be removed under the provision of Section XIV. of the Medical Act, 1858. The revision would be completed this year by the issue of circulars to all those from the letter H to O inclusive. Next year no circulars would be issued, as there would be an election, which would show, so far as the United Kingdom was concerned, the accuracy which is attained by the systematic correction. As no circulars would be issued the opportunity would be taken to clear up the names of those registered as in the Navy, Army, Royal Air Force, and Indian Medical Services, and also those in Colonial Services.

THE ACID-BASE EQUILIBRIUM OF BODY-FLUIDS:

A REVISED NOMENCLATURE.

A good deal of confusion in medical writings on the reaction of the blood has been caused by the use of the same term by different writers in different senses. The various meanings attached to the word "acidosis" are instanced in a recent report[1] of the Medical Research Council, to which we have already referred. We propose to set out certain definitions arrived at by the Hæmoglobin Committee of the Council, in the hope that by the use of a standardised nomenclature many puzzling discrepancies in results may be cleared up.

Concentration of Hydrogen Ions (often expressed cH). The cH of pure water at 22° C. is 10^{-7} g. equivalents (i.e., 10^{-7} g.) per litre, so that in 10 million litres of water there is 1 g. of hydrogen in the ionic state. Pure water at 22° may thus be regarded as a 10-millionth normal acid, also as a 10-millionth normal alkali solution. The degree of actual acidity of any aqueous solution, acid or basic, can always be expressed in terms of normality in hydrogen ion. When, as in water, the concentration of the hydrogen ion is 10^{-7} (grammes per litre), the solution is neutral. Acid solutions have a cH greater than 10^{-7} (e.g., 10^{-6}), while alkaline solutions have a cH smaller than 10^{-7} (e.g., 10^{-8}). The use of negative powers of 10 is a convenience in writing, but it should be borne in mind that these numbers really refer to normality in hydrogen ion. Thus : 1/10,000 Normal H-ion = $N. \times 10^{-4}$; 1/100,000 Normal H-ion = $N. \times 10^{-5}$, and so on, as explained above ; and similarly 1/2000 N. H-ion = 5/10,000 N. = 5×10^{-4} N. ; and 1/5000 N. = 2/10,000 N. = 2×10^{-4} N.

---

[1] Medical Research Council, Special Report Series, No. 72. H.M. Stationery Office. 2*s*. The Lancet, 1923, i., 348.

The pH Nomenclature.—In order to avoid the rather cumbersome type of expression referred to above, a simple abbreviated form of it, suggested by Sörensen, is often conventionally employed. In this mode of expression only the negative exponent is written, and this is designated by the symbol pH. Instead of expressing a 1/100,000 N. H-ion concentration as $[H]^{\bullet} = 10^{-5}$, one simply writes pH 5·0, and instead of writing 2×10^{-4} for a 1/5000 N. solution the shorter expression pH 3·7 is used (since $2 \times 10^{-4} = 10^{-3\cdot7}$). The reaction of water, in this nomenclature, is pH 7·0 (at 22° C.); as the hydrogen-ion concentration rises the pH number becomes smaller, and, vice versa, solutions of pH smaller than seven are acid, those larger than seven alkaline. It should be remembered that the pH notation is merely an aid to writing and calculation, and that the real thing is the hydrogen-ion concentration, cH, which should be used where possible to avoid looseness of thinking and to express the real factor at work.

Buffers.

Everyone who has titrated urine or serum to neutrality with an indicator must have observed that the indicator appears sluggish and the end-point somewhat uncertain. If two separate titrations are carried out with two different indicators—e.g., methyl red and phenolphthalein—it will be found that widely different results are obtained, the former indicator showing a much smaller acidity than the latter. Exact measurements would show that, in the course of neutralisation, the change of H-ion concentration is not proportional to the amount of neutralising substance added. Further, the simple dilution of such a fluid as urine, or blood serum or plasma, with water occasions, over wide limits, no considerable alteration in its hydrogen-ion concentration. The titration of a solution of glycine, or of an acetate or phosphate, shows these remarkable properties even better. Such solutions owe their properties to the presence in them of "buffer" substances.

The properties possessed by such substances in preventing any great change in hydrogen-ion concentrations of a solution on dilution, or when acid or alkali is added to it, appear to have been first made use of by Fernbach and Hubert in 1900. To describe this property they used the word "tampon," in its surgical sense of an absorbent plug. Since the word also means a railway buffer, and was translated into German as "Puffer," it has come into English as "buffer," although this name is not a very appropriate one.

If a strong acid, such as hydrochloric, be added to water, a very small amount raises the hydrogen-ion concentration greatly, because this acid is dissociated into $H^{\bullet}$ and Cl' ions almost completely. Suppose, however, that it is added to a solution of sodium acetate, nearly all of it is replaced by the equivalent quantity of acetic acid. This is a weak acid: that is, it is dissociated to a comparatively small degree. Moreover, so long as any sodium acetate remains, the acetate ions to which it gives rise will greatly depress the ionisation of the weak acetic acid, because a salt such as sodium acetate is highly dissociated into its ions when in aqueous solution. Hence, the increase of hydrogen ions produced by a given addition of a strong acid to an acetate solution is much less than that produced by the same addition to water. The most effective buffers against the addition of acid are, then, salts of weak acids, and against alkali, salts of weak bases. But such salts have another property that renders them still more effective in counteracting the results of such additions. They are hydrolysed, or more correctly, hydrolytically dissociated, in solution in water.

If a solution were perfectly buffered, an addition of acid, or base, or water, to it would effect no change at all in its hydrogen-ion concentration. Such perfectly buffered solutions of course do not exist, though the buffers which are known provide a striking contrast to completely unbuffered solutions such as those of hydrochloric acid or sodium hydroxide.

The Buffers of Blood.—In blood plasma there is an acid-base equilibrium, carbonic acid being the acid,

$$H_2O + CO_2 \rightleftharpoons H_2CO_3 \rightleftharpoons H^{\bullet} + HCO'_3,$$

while sodium bicarbonate functions as the base owing to the low degree of dissociation of the bicarbonate ion, and the production by hydrolytic dissociation of hydroxyl ions,

$$H_2O + NaHCO_3 \rightleftharpoons Na^{\bullet} + H_2CO_3 + OH'.$$

The reaction of the blood plasma, i.e., the concentration of H-ion therein, depends on the relative concentrations of acid (i.e., of dissolved CO_2) and of base (i.e., of bicarbonate). The ratio

$$\frac{H_2CO_3}{NaHCO_3}$$

in blood plasma is of the order of 1/20 as a rule, the $NaHCO_3$ being about 0·03 molar and the H_2CO_3 about 0·0015 m. Sodium bicarbonate, in 0·03 m. solution and in equilibrium with a tension of carbon dioxide just sufficient to prevent appreciable decomposition to the carbonate, has a pH of about 10. A similar solution in equilibrium with pure carbon dioxide at atmospheric pressure has a pH of 6·8. These values are obviously far beyond the limits, in either direction, of the reaction of the blood plasma during life, since the tension of CO_2 to which it is exposed never falls so low or rises so high. To determine pH we have to determine the ratio between free and fixed CO_2, to which it is proportional. The difficulties concern the *absolute* values only—i.e., the magnitude of the factor of proportionality between the bicarbonate and the CO_2 in any given sample, and vice versa. It should be remembered in this connexion that the only free acid of importance in the blood is carbonic acid, since there is always sufficient bicarbonate in the plasma to combine with other acids which are stronger than it, and which may diffuse into the blood from the tissues in which they are produced. Weaker acids—e.g., the acid radicles of proteins—are, of course, free in a proportion depending on their strength.

Reaction; Reaction of "True Plasma."

By *reaction* is meant the degree of acidity or alkalinity as determined by hydrogen-ion concentration. Blood normally is alkaline—i.e., its cH at 22° C. is smaller than 10^{-7}, and its pH greater than 7·0. At 38° C. the values for neutrality are $1\cdot83 \times 10^{-7}$ or pH = 6·74. When we speak of the reaction of a blood, however, we really refer only to *the reaction of the plasma as it actually exists in that blood*—i.e., in contact with the corpuscles, and at the particular pressure of CO_2 prevailing in the blood. When plasma is separated off from the corpuscles, without alteration of the CO_2 pressure, its reaction is identical with that determined for the blood at the time of separation; such a plasma has been termed "*true plasma*" by Joffe and Poulton. At no CO_2 pressures, other than that at which the plasma separation was effected, are the reactions of blood and of *separated* plasma identical. At CO_2 pressures lower than that at which separation was effected the whole blood is less alkaline than the separated plasma, and at CO_2 pressures higher than that at which separation occurred the relation is reversed. This means that whole blood is a better buffer than plasma. Of the reaction of the corpuscular contents we have little certain knowledge, though there is some evidence that it is more acid than the plasma.

Ketosis.

In many pathological states, and in starvation, abnormal substances appear in the urine and in the breath; these substances comprise the following: β-oxybutyric acid, aceto-acetic acid, and acetone.

The last of these is probably derived from the second by loss of CO_2, while the second and the first are related by oxidation and reduction of the secondary alcohol and ketone groups. Aceto-acetic and oxybutyric acids are probably normal intermediary products of fat metabolism, and it is often as a result of disordered fat metabolism that these substances appear, the first two in the urine, and the acetone in urine and breath. Stadelmann in 1883 observed the excessive excretion of acid in true diabetes and originated the acid intoxication theory of diabetic coma. Naunyn in 1898 gave the name "acidosis" to the condition in which aceto-acetic and oxybutyric acids occurred. More recently the name "acidosis" has been extended by many workers to mean also an increased acidity or a lowered bicarbonate content of the blood, as well as the appearance of abnormal acids and of acetone in the urine and breath. There has resulted a considerable confusion of nomenclature on account of this double meaning of the word, which it is now proposed to discard altogether by calling the condition which Naunyn originally designated acidosis, by the name "*ketosis.*"

Acidæmia; Alkalæmia.

For conditions in which the reaction *of the circulating blood* is less alkaline than normal, whether accompanied by ketosis or not, it is proposed, where a name is used, to employ the term "*acidæmia,*" while for the condition in which the blood is abnormally alkaline the term "*alkalæmia*" is suggested. These terms obviously are only applicable to blood. It is, however, by no means essential to adhere to any particular name even for blood, since the expressions "increased cH" and "lowered cH" may be used with equal convenience for all body fluids or tissue cells. A change of reaction in the arterial blood need not necessarily mean a change of reaction to the same extent in the tissue cells, for the latter would depend also on the local metabolism and circulation. In all probability the condition of ketosis is not necessarily associated with any specific alteration in blood reaction either in the one direction or in the other.

Bicarbonate Content, Alkali Reserve, Carbon Dioxide Fixing Power, and Titratable Alkalinity.

The term "*alkali reserve,*" introduced by Van Slyke, has almost the same significance as the expression "bicarbonate content." It means the volume of carbon dioxide measured dry and at N.T.P., which can be expelled by acid from 100 volumes of blood or blood plasma, which has been brought into equilibrium with normal alveolar air (40 mm. CO_2) at a given temperature, the volume of gas held in physical solution being deducted.

The alkali reserve of plasma or serum is obviously a measure of its bicarbonate content, but the meaning of the former term when applied to whole blood is less definite. There seems in fact to be no necessity for the use of the somewhat ambiguous term "alkali reserve," since the terms "bicarbonate content" for plasma and "carbon dioxide fixing power" or "fixed carbon dioxide" for blood more accurately denote what is meant. The bicarbonate content of the true plasma is one of the important factors in determining its reaction.

The term "*titratable alkalinity*" refers to the alkali content of plasma or serum, as determined by titration with standard (1/50th N.) acid, using an indicator; Zuntz employed litmus paper for this purpose. Owing to the presence of variable quantities of carbon dioxide in the titration mixture, and to the presence of phosphates and proteins, the end-point obtained will vary over a somewhat wide range, especially if different indicators are used.

These definitions and the method of graphic representation used having been clearly set out, the rest of Part I. is devoted to the technique of the determination of the reaction of the blood by direct and indirect methods and to a discussion of the buffers of the blood and tissues.

A Model Investigation.

Part II. contains an account of an investigation, which might well be taken as a model of scientific reasoning applied to physiological and pathological problems, into the relation of changes in the hydrogen-ion concentration of the blood to pathological conditions of the body. It is pointed out that though the hydrogen-ion concentration of the arterial blood differs but little in different normal individuals, it is not exactly the same in all persons.

Alterations under normal conditions have been observed by all the methods of estimation. It is clear that within the range of physiological conditions measurable variations in hydrogen-ion concentration may also be observed in the blood of the same individual. The simplest case to be noted is that of physical exercise. On the other hand, Hasselbalch and Gammeltoft found that during pregnancy there was no detectable alteration in the reaction of the blood at alveolar CO_2 pressure, although the CO_2 fixing power was diminished.

Since it is established that there is a change in hydrogen-ion concentration in health and an even greater one in disease, the question naturally arises, Of what significance is the altered reaction of the blood? To what extent is it responsible for the symptoms? To what extent is it the fundamental alteration in the organism? The steps by which an answer to these questions should be approached is outlined in general terms and with special reference to one symptom, dyspnœa. The general plan is that first, an inquiry may be made as to what changes are produced by altered reaction in the blood during health. Secondly, the question may be asked, Are such changes prominent as symptoms during disease? Thirdly, if so, is there such a change in the hydrogen-ion concentration of the blood as would account for the symptom? If such a change occurs the simplest hypothesis is that the change of alkalinity (or acidity) is the cause of the symptom in question.

To take a specific instance—a certain symptom, dyspnœa, may be selected. Does increased hydrogen-ion concentration cause breathlessness during health? Is dyspnœa associated with increased hydrogen-ion concentration of the blood during disease? If so, the simplest assumption is that the increased hydrogen-ion concentration in disease causes the breathlessness.

"The simplest assumption" does not necessarily constitute proof. The dyspnœa may have some quite other cause than hydrogen-ion concentration. If, however, it be granted that the hydrogen-ion concentration is a cause of dyspnœa during rest, then, before discarding it as a cause during disease, reason should be shown why the brain ceases to be sensitive to it during the malady, and some other stimulus must be discovered.

A Summary of the Information Obtained.

Proceeding on these lines, much information of value was obtained. For the experimental and theoretical data on which the conclusions were based reference must be made to the report. The conclusions are summarised below.

Influence of cH on the Activity of the Respiratory Centre.

The activity of the respiratory centre is definitely influenced by changes in the hydrogen-ion concentration, in the oxygen concentration, and in the temperature of the blood reaching it. A change in hydrogen-ion concentration may be the primary cause of the alteration of the activity of the respiratory centre. Under other circumstances the primary factor may be either shortage of oxygen or rise of temperature: both these conditions cause increased breathing and therefore will in themselves tend to cause alkalæmia. Here the change in reaction of the blood is a secondary factor, but directly it is established its influence will obviously have seriously to be taken into account. The sensitiveness of the respiratory centre to changes in hydrogen-ion concentration is so great that an apparently trifling alteration of hydrogen-ion concentration in the blood may result in great changes in the breathing.

The Reaction of the Blood during Exercise.

(1) Increased hydrogen-ion concentration in the blood is a cause of hyperpnœa.

(2) It is not necessarily the sole cause.

(3) The hyperpnœa resulting is rather of the deep than the rapid type.

(4) In the absence of some other factor which lowers the response of the respiratory centre increased c_H must, if it exists, cause some degree of hyperpnœa.

In the application of the above principles to diseased conditions the time factor must not be forgotten. We have really no knowledge of what physiological response might be evoked by an increased hydrogen-ion concentration acting for weeks or months in the blood of an otherwise normal person.

Conditions in which Acidœmia or Alkalœmia has been Alleged to Exist.

The Relation of Acidœmia to Breathlessness in Diabetes, Urœmia, and Cardio-Renal Cases.—In certain of the above, namely, frequently in uræmia and in certain groups of cases, especially such as are associated with no simple cardiac lesion, there is an acidæmia. In the absence of proof to the contrary this acidæmia must be regarded as a contributory cause of breathlessness. In a certain number of miscellaneous cases there is no acidæmia; in such, therefore, the breathlessness is not attributable in any degree to that factor, whilst in diabetes the acidæmia is often quite insufficient to account for the hyperpnœa. The same is even more emphatically true of simple cardiac cases in which there is an alkalæmia. At present it seems to be impossible to assign to breathlessness a universal cause.

Such, then, is the road to breathlessness via acidæmia; there is, however, another road to breathlessness which also involves a change in the reaction of the blood—namely, that which is associated with alkalæmia. This broad distinction between cause and effect may be recognised—when acidæmia is associated with breathlessness the acidæmia is a cause of the breathlessness, when alkalæmia is associated with breathlessness the breathlessness is the cause of the alkalæmia.

The Services.

ROYAL ARMY MEDICAL CORPS.

Maj. and Bt. Lt.-Col. A. W. Gibson to be Lt.-Col., vice Lt.-Col. F. J. Palmer, retd. pay.

Capt. and Bt. Maj. W. McNaughtan retires, receiving a gratuity, and is granted the rank of Maj.

Capt. D. T. M. Large to be temp. Maj. whilst empld. as Dep. Asst. Dir. of Pathology.

Capt. J. H. Barry retires, receiving a gratuity.

Temp. Capt. A. W. Comber relinquishes his commn. and retains the rank of Capt.

Temp. Capts. M. J. MacGregor and E. W. Bacon retain the rank of Capt. on ceasing to be empld. as Dental Surgs.

J. L. Newton to be temp. Lt. whilst empld. as Dental Surg.

ARMY RESERVE OF OFFICERS.

Lt.-Col. S. J. C. P. Perry, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

Capt. E. B. Hinde, from T. A. Res., to be Capt.

Capt. E. G. Howell (late R.A.M.C.) to be Capt.

Lt. R. M. Savege (late R.F.A., T.F.) to be Lt.

Lt. E. R. Woodroofe (late K.O.Y.L.I.) to be Lt.

The undermentioned officers, having attained the age limit, are retired, and retain their rank, except where otherwise stated: Lt.-Cols. Sir S. F. Murphy and D. S. Davies; Majs. D. T. Belding (Bt. Lt.-Col.), H. R. Kenwood (granted the rank of Lt.-Col.), E. Walford, D. Rennet (Bt. Lt.-Col.), R. A. Dunn, W. B. Barclay, M. G. Yunge-Bateman, and R. A. Farrar; Capt. A. G. R. Foulerton (Bt. Maj.) (granted the rank of Maj.), T. H. Ward (Bt. Maj.), W. Robertson (granted the rank of Lt.-Col.), J. A. Gibson, G. H. Weston, A. H. Bygott, A. E. Williams, D. T. R. Jones, A. H. Lowe, R. A. Lyster, A. Gregor, R. J. Fleming, C. M. Fegen (Bt. Maj.) (granted the rank of Maj.), G. L. Travis, A. N. Stevens, S. W. Wingfield, R. W. Brearey, E. L. Gaunt, T. Edwardes, J. T. A. Walker, W. J. M. Slowan, J. Crawford, W. K. Parbury (granted the rank of Maj.), J. H. Wood, E. B. Pike, G. Q. Lennane, F. G. Rose, J. Mair, A. C. Williams, G. S. Hoffman, H. D. Tebbitt, K. B. Williamson, E. P. Wheeler, G. S. Elliston, W. F. Lanchester, W. H. Hill, A. Reid, and W. H. Biggs; Lt. A. W. Bartlett.

Capt. D. Embleton relinquishes his commn. and is granted the rank of Maj.

Capt. F. T. C. Linton relinquishes his commn. and retains the rank of Capt.

TERRITORIAL ARMY RESERVE.

Capt. R. P. Nash, from 2nd Eastern Gen. Hospital, to be Lt.-Col.

Capt. T. H. W. Alexander, from 1st Scottish General Hospital, to be Maj.

The following, having attained the age limit, are retired and retain their rank: Lt.-Col. S. M. Copeman; Maj. A. A. Mussen; Capts. G. L. Eastes, C. D. Edwards, and C. A. Molony.

Capt. D. Smith relinquishes his commn. and retains the rank of Capt.

"Audi alteram partem."

OXFORD CONTRIBUTORY HOSPITAL SCHEME.

To the Editor of The Lancet.

Sir,—It may interest your readers to hear how the Oxford Hospital Scheme has fared during the past two years. The scheme was started in September, 1920. A contributor is asked to subscribe 2*d.* per week, children of wage-earning age 1*d.*, until they are earning an adult's wage. In the case of married couples, when the husband and wife each subscribe 2*d.* a week, their children are entitled to treatment up to wage-earning age. Every care is taken to prevent those who are in a position to pay for adequate medical advice from joining. No contract is made with the contributors. In 1921 the scheme brought the hospital a little over £17,000, but we had yet to enrol a number of villages and firms. In 1922 the scheme brought the hospital a little over £23,000. When one learns that in 1913 the total income of the hospital from all sources amounted to £9559, one realises how much those who use our hospitals can do towards keeping them on a voluntary basis.

We were told at the outset it would be impossible to get agricultural labourers voluntarily to subscribe as much as 2*d.* a week; they have done so, and in spite of the enormous reduction in their wages they still continue to do so. We have organised hospital aid committees in 295 villages, and in the towns, including the city itself, we have aid committees in every parish. In this way over 2000 people are working for, and interested in, the maintenance of our hospital on a voluntary basis, who a few years ago scarcely gave the hospital a thought. A very large number of meetings have been organised in the villages. At these meetings the speakers explain why both surgical and medical work has become so much more expensive, why it is important to keep our hospitals on a voluntary basis, and why those who are present should join. Perhaps one of the most striking instances of the way in which those can help who have a mind to is the fact that last year the employees of two shops in Oxford from which the hospital obtained nothing in 1919 contributed between them £230 5*s.*

The following statement of accounts and statistical examples may be of interest.

Radcliffe Infirmary and Oxford County Hospital—Weekly Contribution Scheme: Financial Statement.

1921.	£	*s.*	*d.*	*1922.*	£	*s.*	*d.*
Received during the year and to Jan. 10th, 1922	16,281	11	1	Received during the year and to Jan. 10th, 1923	21,538	5	7
Received during 1922 in respect of 1921	1,150	4	3	Amount received for fourth quarter after Jan. 10th, 1923	1,521	4	1
	£17,431	15	4		£23,059	9	8

Increase on year—£5,627 14*s.* 4*d.*

Expenditure.

1921.	£	*s.*	*d.*	*1922.*	£	*s.*	*d.*
Appeals	926	12	6	Appeals	463	19	1
Salaries and wages	538	1	9	Salaries and wages	582	10	0
				Sup. Fund	21	19	0
	£1,464	14	3		£1,068	8	1

Decrease of expenditure—£396 6*s.* 2*d.*

Typical Examples of Increased Income from Market Towns and Villages.

The amounts in these statements have been brought to the nearest pounds.

The total cost of working the scheme comes to a little less than 4½ per cent. of the amount collected.

I am, Sir, yours faithfully,
Oxford, March 13th, 1923. WM. COLLIER.

SYPHILIS OF THE MEDIASTINUM.

To the Editor of THE LANCET.

SIR,—I have read with great interest Dr. H. F. Renton's admirable description of his case in your last issue. I wish, however, that the title had been *A Possible Case of* Syphilis of the Mediastinum, for the case must, I think, be regarded as not proved. In almost every detail it reads like a classical case of mediastinal sarcoma. In this disease it is the usual thing to find "no displacement of viscera"; in fact, the heart may be completely enveloped by growth but not displaced. Again, it is usual to have "no obvious wasting until late in the disease." This is a very characteristic feature of mediastinal sarcoma. And further, the intermittent nature and the change in the character of the dominant symptoms are what one often sees, and therefore many of the points adduced as evidence of syphilis of the mediastinum are equally in favour of sarcoma. Doubtless the patient had syphilis as well, and curiously enough, I have seen two or three cases recently of primary malignant disease of the thorax, where there has been evidence of syphilis and a strongly positive Wassermann reaction; and it is not uncommon to see carcinoma on top of a chronic superficial glossitis.

I write this in no spirit of carping criticism, but opinions are so divided as to the frequency of syphilis of the lungs and the mediastinum, and the subject is one of such obvious importance that any contribution to the subject of proved cases is of value. It is a thousand pities that post-mortem examination is so often refused in these important cases.

I am, Sir, yours faithfully,
F. G. CHANDLER.
Harley-street, W., March 19th, 1923.

ANNULAR SHADOWS IN THE RADIOGRAM.

To the Editor of THE LANCET.

SIR,—In the interesting paper by Dr. Bernard Hudson and Mr. P. G. Sutton in THE LANCET of March 17th on X Ray Examination of the Chest, an account is given of the case of a male patient who showed no physical signs of tuberculous disease, but whose radiogram alone gave information of his complaint. The excellent radiogram shown in Fig. 6 in the article is given to illustrate the point that the writers wish to make, that the radiogram may sometimes be the sole means by which a diagnosis can be made. I do not in any way dispute this statement, for my own experience also leads me to believe that a case of some length of standing (as contrasted with an early case) may show quite extensive abnormal markings in a radiogram without giving any physical signs by the usual methods of examination, yet it must be remembered that the annular shadows shown in Fig. 6 may be explainable by other means. Dr. Burns Anderson, in an article on Roentgenographic Pleural Annular Shadows in Pulmonary Tuberculosis in a recent number of the *American Review of Tuberculosis*, has dealt with this subject at length. The existence of circular shadows in chest radiograms is of common occurrence, and they are certainly not all cavities, probably many are pleural. I have under my care at present two cases, which both show very clearly such circular shadows in all X rays taken of them, one of these was sent with a diagnosis of cavitation founded on this appearance. In both these cases I have little doubt from the absence of other symptoms and signs that the shadows are of pleural origin, and though Dr. Hudson's case may not be of this nature, further explanation will be required before the appearance shown could be accepted as due to a cavity. So large is the circle seen that the cavity must be as large as a golf ball in the original subject. Is it not the case that a cavity of that size in that particular position above the clavicle *must* give physical signs? The non-existence of a fluid level in the circle is also against its being a cavity, as is also the thinness of the fibrous layer around it, although these are not absolute contra-indications. The after-history of the case and further radiograms should aid in clearing up the question.

With Dr. Hudson's conclusions probably everyone would agree, especially that an inexpert opinion on a radiogram is often misleading.

I am, Sir, yours faithfully,
Penmaenmawr, March 18th, 1923. C. H. BRODRIBB.

THE ÆTIOLOGY AND OPERATIVE TREATMENT OF HALLUX VALGUS.

To the Editor of THE LANCET.

SIR,—Mr. E. Muirhead Little in your issue of March 10th (p. 509) expresses the opinion that there is no transverse arch of the foot formed by the heads of the metatarsal bones, and asks for proof to be produced of its existence by anyone who may think that he possesses it. I have performed a considerable number of the operation described by Dr. Sandelin and advocated by Mr. Little for hallux valgus—viz., excision of the head of the first metatarsal bone, and, like Dr. Sandelin, have had many expressions of satisfaction with the result from my patients. The "bunion pain" which accompanies the arthritis is got rid of by this operation, and the patient can get about with much less discomfort than before and is usually becomingly grateful.

But the foot is not normal; either the patient assumes a gait somewhat plantigrade in character, by bearing weight on the inner border of the foot posterior to the neck of the divided metatarsal bone, or a normal position of the foot is preserved by—more or less instinctively—flexing the outer toes and using them to replace the absent metatarsal head. Examine the foot of a patient, say, a year after the operation, and usually one or more corns will be found on the parts which have had to bear pressure as the result of the drop of the foot; and the alteration in the shape of the foot is one which gradually becomes worse, sometimes for years. Moreover, careful inquiry will elicit the fact that care has to be constantly exercised in walking on cobbles or other irregular surfaces; the operated foot must be put on to a flat surface or it may twist and cause pain. And in going down hill the patient soon becomes aware that the smaller toes are taking the place of the absent inner pillar of the transverse arch, and I have seen toes badly rubbed and blistered after a far from strenuous scramble in a patient who before the operation was accustomed to moorland walks and climbing.

There is another operation which gives as satisfactory results as excision of the head of the metatarsal bone and has not its drawbacks. This is excision of the base and three-quarters of an inch of the shaft of the proximal phalanx, plus removal with chisel or bone-forceps of the overgrown boss of bone about the inner side and dorsum of the head of the first metatarsal. The patient can begin to get about three or four days after the operation, convalescence is decidely easier than after the older operation, and there is practically none of the relative disability which follows the latter.

I have in my household two members, one of whom has had the metatarsal excision, and the other the phalangeal excision, done for crippling degrees of bunion of both feet. Daily observation for some years has convinced me that the result of the phalangeal operation is as nearly perfect as possible; the result of the metatarsal operation has been considerably improved by the patient having a bar of leather nailed on the sole of each shoe or boot in the position corresponding to the necks of the metatarsal bones, as suggested by Sir Robert Jones, the weight being borne on this bar, which replaces the no longer existing transverse arch of the foot.

I am, Sir, yours faithfully,

Bradford, March 10th, 1923. JAMES PHILLIPS.

"STERILITY IN WOMAN."

To the Editor of THE LANCET.

SIR,—I am greatly indebted to your reviewer for his generous criticism of my book with the above title, and I am glad that he has called attention to my definition of sterility: "the inability of a woman to bring forth living children" (THE LANCET March 17th, p. 546). I should like to make it quite clear that I have chosen it advisedly. This definition is much the same as that of Matthews Duncan. I have been careful to say that there are differences of opinion concerning the word, and that I disagreed with those who considered that when once the ovum has been fertilised sterility could no longer be said to exist. Your reviewer's opinion, which he considers a truer definition than mine, is the same as that of Kisch—viz., "failure to conceive under favourable conditions." Of course, inability to conceive must mean sterility, but I maintain that conception is not fertility, that repeated conception may be followed by sterility, and that if a woman cannot produce a living child she is sterile so far as the State is concerned, however many still-births she may have had. I also say that modern surgery prevents many women from being classed as sterile; hence my mention of Cæsarean section in the chapter devoted to operative treatment.

I am, Sir, your faithfully,

R. A. GIBBONS.

Cadogan-place, S.W., March 19th, 1923.

THE OPERATIVE TREATMENT OF SEPTIC MENINGITIS.

To the Editor of THE LANCET.

SIR,—All will agree with Sir William Milligan (THE LANCET, March 17th, p. 563) that the earliest possible diagnosis, which is essential for success in cases of meningitis, can only be made with certainty by an examination of the cerebro-spinal fluid. But it cannot be accepted that no case should be regarded as one of septic meningitis unless organisms are found in the cerebro-spinal fluid, because Mygind has stated that in 70 per cent. of 133 fatal cases of undoubted otogenic meningitis confirmed by post-mortem examinations the cerebro-spinal fluid obtained before death was sterile. Jenkins has also written that in a number of his cases of meningitis the cerebro-spinal fluid was sterile. I have the notes of 13 of my own fatal cases (and there are others without notes) in which the cerebro-spinal fluid was sterile in six. The diagnoses were again confirmed by post-mortem examinations. These cases were seen much too late, and the clinical diagnosis was manifest before lumbar puncture was performed.

In addition, Mygind considers that the diagnosis of meningitis by the chemical tests for the reduction of Fehling's solution are unreliable, and in four of the 13 cases mentioned above the cerebro-spinal fluid remained alkaline and reduced Fehling's solution. Therefore *the* valuable test for early diagnosis, as Mygind and Jenkins have stated, is the increase in the number of cells in the cerebro-spinal fluid. This pleocytosis occurs as early as three hours after the onset of meningitis, and turbidity, which is next in importance, occurs in 12 to 36 hours.

The method I now adopt is to have the cerebrospinal fluid examined with a Fuchs-Rosenthal cytometer while I am operating on the mastoid, no time being lost in waiting for the result of a bacteriological examination which can be done later.

I am, Sir, yours faithfully,

London, March 18th, 1923. EDWARD D. D. DAVIS.

To the Editor of THE LANCET.

SIR,—I read with interest Mr. H. L. Martyn's paper in THE LANCET of March 10th, dealing with the treatment of a case of septic meningitis of aural origin, and also your annotation on this subject. May I ask a short space to point out that Mr. C. E. West and Mr. S. R. Scott were the first to suggest and successfully carry out the operation of translabyrinthine drainage for leptomeningitis. I hope to publish shortly in the *Journal of Laryngology and Otology* a detailed abstract of the original paper on Septic Meningitis of Aural Origin, which I read before the Tenth International Congress of Otology.

I am, Sir, yours faithfully,

Wimpole-street, W., March 16th, 1923. G. J. JENKINS.

THE SAFETY OF ETHER AS AN ANÆSTHETIC.

To the Editor of THE LANCET.

SIR,—I read in THE LANCET of March 10th, with much interest, a paper by Dr. W. J. McCardie, of Birmingham, at the Section of Anæsthetics of the Royal Society of Medicine, and I note with satisfaction the high encomium the writer of the paper paid to the ether inhaler bearing my name and devised by me considerably more than 40 years ago. Its use and efficiency I first demonstrated in University College Hospital in January, 1877, when I brought it before the London profession and administered ether with this inhaler to several patients of the late Mr. Christopher Heath. As an inhaler, its simplicity, efficiency, and portability, I am glad to see, still hold the field, being used extensively all over the world where surgery is known. The small quantity of ether used to produce the different degrees of anæsthesia is well known and fully appreciated by so many practical and distinguished anæsthetists that it would appear to me to be quite unnecessary to say anything more in its favour.

I wish to mention I had many conversations with the late Sir Frederic Hewitt regarding its merits, and in his valuable work on Anæsthetics he gave a full illustrated description of it and stated it was the inhaler he nearly always employed. In the discussion which followed the reading of Dr. McCardie's paper I was pleased to observe what Dr. Carter Braine, one of London's most experienced and practical anæsthetists, said in praise of the inhaler. In view of the comparative safety of ether and the dangers of chloroform, I think it right to say I am still as strong in my views on this subject as I was nearly half a century ago when I produced a table of statistics, collected by Dr. Andrews, of Chicago, and those collected in England by Dr. Richardson—these combined statistics proved at a glance the absolute and relative mortality caused by the several anæsthetic agents used at that time. Furthermore, these statistical tables indicated beyond all manner of doubt that chloroform was eight times more dangerous than ether when used as an anæsthetic.

I am, Sir, yours faithfully,
LAMBERT H. ORMSBY, M.D., F.R.C.S.I.,
Senior Surgeon, Meath Hospital and co. Dublin Infirmary.
Dublin, March 13th, 1923.

THE OPPOSITION TO PANEL PRACTICE.

To the Editor of THE LANCET.

SIR,—It is obvious that the insured person who also pays private medical fees must be persuaded in his mind that he is getting something thus that he would not get otherwise. This requires no comment. What I objected to was your specific charge that non-panel doctors provided this persuasive influence.

You said "a certain number," and I asked if you could name one. It is one thing to say people have been persuaded: it is another thing to say they have been persuaded by certain specified individuals. It is just as if while walking along the Strand my watch disappears from my pocket. I might quite safely say it had been stolen, but I should hardly be justified in saying it had been stolen by some members of the editorial staff of THE LANCET.

Your words were quite clear. The unhappiness was not in the choice of words, but in making a charge against a respectable body of men which you are not prepared to substantiate. If this is so the proper thing is to say you are sorry.

I am, Sir, yours faithfully,
March 13th, 1923. GEORGE F. GRANT, M.B., C.M.

*** The words whose ambiguity we have already acknowledged were as follows:—

> There exist a certain number of doctors who, being hostile to the Act, do not go on the panel, and persuade patients that they get better treatment by attendance as private patients.

The meaning of the passage is that the existence of doctors who are not on the panel, and who are hostile to the Act, persuades patients, &c. . . . The corollary is that the patients are persuaded, or persuade themselves, &c., or they would not make two payments.—ED. L.

ALCOHOL AND INSANITY.

To the Editor of THE LANCET.

SIR,—I am unfortunately not in a position to demonstrate any of the "other factors" of insanity for which Dr. W. C. Sullivan asks in his letter published in your issue of March 10th. Distinguishing, however, between ultimate and immediate causes it is commonly believed that mental stress is often the immediate cause of insanity, and in view of the almost universal acceptance of this relationship it seems to me that the onus of disproof is on Dr. Sullivan. It may safely be said that the period of the war was one of very greatly increased mental stress.

Although, I believe, literally correct in my original statement it might perhaps have been well had I, instead of saying that other factors of insanity must be presumed to have been more active, said may be presumed and then my argument holds—viz., unless it be shown that other factors did not increase (and if alcoholism be not the cause then other causes must exist and may have increased) at a rate corresponding with the fall in alcoholism then the latter may still be the cause of insanity in spite of the facts observed during the war.

Dr. Sullivan evidently fails to distinguish between what I admit as a fact and what I admit as a valid argument in favour of that fact. Many correct conclusions are made by incorrect methods of reasoning. If alcoholism as a cause of insanity be negligible and other causes have increased it follows, as Dr. Sullivan points out, that the incidence of insanity should have increased considerably instead of but slightly. But I do *not* admit that alcoholism is negligible; I purposely take the opposite position in order to point out the several things which must be proved before the thesis can be established that alcoholism does not cause insanity.

I am, Sir, yours faithfully,
STANLEY WYARD.
Wimpole-street, W., March 19th, 1923.

THE TREATMENT OF MENORRHAGIA.

To the Editor of THE LANCET.

SIR,—May I take the liberty of thanking you for the excellent series of special articles on Modern Technique in Treatment which are now appearing in THE LANCET?

Would you consider introducing into the series an article on menorrhagia in young women where there is no obvious anatomical lesion? I am sure that many general practitioners must be frequently meeting with such cases and finding difficulty in their successful treatment.

I am, Sir, yours faithfully,
B. VENN DUNN, M.D. Edin.
Loughborough, March 14th, 1923.

*** The subject is already being dealt with, and we shall publish the article shortly. We thank Dr. Venn Dunn for the terms of his letter, and shall be grateful to receive from readers suggestions as to future articles.—ED. L.

A NEW GENERAL ANÆSTHETIC.

To the Editor of THE LANCET.

SIR,—It was my good fortune in January last to be present at three administrations of Narcylen, a new general anæsthetic discovered by Prof. K. Gauss, of Freiburg. It consists simply of purified acetylene and oxygen, the objectionable smell being largely masked by the addition of oil of pine. Acting upon a suggestion of Prof. W. Straub that the anæsthetic properties of acetylene might prove of use in general surgery, Gauss decided to experiment with it. When administered to frogs it was found they quickly went to sleep. Straub's assistant next pluckily consented to be subjected to experimentation, and the gas, combined with oxygen, was cautiously given him. Using a percentage of acetylene 40, oxygen 60, he became insensible to pain in less than five minutes. Gauss next successfully anæsthetised a number of his students. Narcylen was next employed upon a patient requiring a minor operation, and its use was gradually extended, so that to-day at the Diakonissen House Hospital no other general anæsthetic is employed. Up to the time of my visit Gauss had used Narcylen in 515 cases with no catastrophes.

The advantages claimed for the new anæsthetic are that induction is rapid, simple, and safe, without struggling or excitement, while recovery is equally rapid. Relaxation is not so complete as that obtained with chloroform, but is sufficient for major operations. Respiration is a trifle quicker than normal; the patients do not change colour, and appear to be in a natural sleep. The patient's temperature usually drops one degree below normal. There is little or no post-anæsthetic vomiting.

Unfortunately, I was only able to be present at three cases in which Narcylen was employed, but I saw enough to impress me with the possibilities of the new gas. I chatted to a number of women in the different surgical wards, who had been operated upon some days previously; they all testified to the absence of unpleasant sensations either during induction or subsequently when they awoke. Gauss has employed the new anæsthetic in several cases to diminish the pangs of childbirth, but admitted that, like all other general anæsthetics, its effect was to diminish uterine contractions.

I am, Sir, yours faithfully,
CHARLES H. S. HORWITZ, M.R.C.S. Eng.,
Resident Physician, London Home of Twilight Sleep,
Streatham Manor, Streatham, S.W.
March 5th, 1923.

GANGRENE OF THE TOES FOLLOWING CONSUMPTION OF ERGOTISED RYE BREAD.

To the Editor of THE LANCET.

SIR.—In their letter in your issue of March 17th Mr. R. E. Kelly and Dr. W. J. Dilling write that it would be of interest to know on what grounds I excluded the possibility of ergotism as an ætiological factor in the cases of thrombo-angiitis obliterans known to me. I have not absolutely excluded the possibility, but it seems to me *almost impossible* that all the patients in question consumed ergotised rye bread. Was ergotised rye bread consumed by all the patients known to Dr. Leo Buerger and other writers on the subject in America? Is one to imagine that, if ergotised rye bread can be obtained in England and America, only Hebrews and only male Hebrews eat it, or that scarcely anyone excepting a male Hebrew is liable to be badly affected by it? It is interesting to hear that the investigations into the ergot question are being continued. All those who, as I myself, often eat bread made partly of rye, and do not wish to consume ergot with it, will certainly welcome any investigations on the subject.

I am, Sir, yours faithfully,

London, March 17th, 1923. F. PARKES WEBER.

Medical News.

UNIVERSITY OF DUBLIN.—A meeting of the Senate was held on March 10th to nominate for honorary degrees. Among the names submitted by the Board and approved by the Senate are Dr. William James Mayo, of Rochester, U.S.A., and Dr. Ernest Hastings Tweedy, of Dublin.

UNIVERSITY OF MANCHESTER.—At the next graduation ceremonial the degree of Doctor of Science will be conferred on Prof. Frederick Gowland Hopkins, F.R.S., and Prof. Niels Bohr, Ph.D., Director of Theoretical Physics, Copenhagen. Dr. Bohr was formerly Reader in Mathematical Physics in the University of Manchester.

THE honorary degree of Doctor of Laws of McGill University, Montreal, is to be conferred on Sir William Taylor, K.B.E., a past President of the Royal College of Surgeons in Ireland, and Regius Professor of Surgery in the University of Dublin. Other recipients of the degree at the same time will be Sir Berkeley Moynihan and Sir Robert Jones.

UNIVERSITY OF BIRMINGHAM.—A post-graduate course of lectures and demonstrations on Crime and Punishment will be held during May, 1923. Dr. W. A. Potts will deal with Mental Defect, and Dr. Percy Hughes with Insanity, with special reference to Crime and Punishment, while the subject will be generally treated by Dr. Hamblin Smith. Visits will be paid to Barnsley Hall Asylum, Great Barr Hall Park Colony, Mental Deficiency Office, Monyhull Colony, and H.M. Prison, where demonstrations will be held. Further particulars may be obtained from the Dean of the Medical Faculty.

PRINCESS ALICE MEMORIAL HOSPITAL, EASTBOURNE. Every effort is to be made to keep up the subscriptions on behalf of this institution. At the end of 1920 the deficit amounted to £2405 0*s.* 7*d.* This was reduced during 1921 to £1663 12*s.* 2*d.*, but 1922 again showed an upward tendency, the deficit at the end of the year being £1848 10*s.*, representing a loss of £185 on the year's working. There were, however, several big items of expenditure last year which will not recur, a new anæsthetic room, a new dispensary, a new boiler house and boiler for heating the theatre, a new boiler for hot-water service and massage, and treatment rooms for war pensioner out-patients. These improvements swallowed up £941. The total receipts amounted to £12,093 1*s.* 8*d.*, and the payments £12,277 19*s.* 6*d.* To the latter had to be added last year's deficit, making the total expenditure £13,941 11*s.* 8*d.* A notable feature in the accounts was a saving of £567 in the cost of food. At the annual meeting of the governors on March 16th Sir Charles O'Brien Harding paid tribute to the work of the matron, and alluded to the establishment, under the direction of Dr. F. R. P. Taylor, of a clinic for nervous disorders.

THE Minister of Health has appointed Mr. A. N. Rucker, of the Ministry of Health, as his assistant private secretary.

MORE SMALL-POX IN DERBYSHIRE.—At the end of last week four new cases were reported at Clowne, Derbyshire, making a total of 80. People in the district are being vaccinated at the rate of 500 a week.

DIPHTHERIA IN CHESHIRE.—An outbreak has occurred in the Compstall district, and 16 cases have been sent to hospital. Further investigation revealed a number of carriers amongst pupils and teachers in the schools, and these also have been dealt with. The disease has also appeared in Derbyshire and four cases have been sent to Chinley Hospital.

MENTAL TREATMENT REFORM.—The Lord Chancellor (Viscount Cave) was present at the annual meeting on March 17th of the Mental After-Care Association at Merchant Taylors' Hall, London Wall, E.C. In moving the adoption of the Association's report, Lord Cave expressed appreciation of the work of the Association, and stated that the position of those who needed mental treatment, or who were recovering from mental affliction, had been engaging the special attention of the Government. Better machinery was required for the mental treatment of cases still of a doubtful character, which might be easily curable, before resort was had to the machinery allowed by the present law. They needed provision for mental treatment without certification or any formal step of that kind. He had reason to believe that proposals would shortly be made under which that treatment might be given. It needed to be very carefully done. A second point that was receiving the attention of the Government came specially within the scope of the work of the Association. He meant the after-care of those who had recovered, and he hoped and believed that visiting committees might shortly be given further and greater powers in that direction. Further facilities for research and investigation might also well be granted to those who had the care of persons suffering from mental diseases, and he hoped that step might shortly be taken. Sir Charles Wakefield, President of the Association, said that the number of cases applying for assistance during the past year showed a further increase, being 944, as against 874 in 1921 and 379 in 1915. A deficit at the end of 1922 of £740 was a heavy burden, considering the limited resources of the Association. Patients and their friends had contributed substantially to the funds, and this, with the official recognition of the value of their work, gave them confidence that they would in time obtain public support upon a wider basis.

DONATIONS AND BEQUESTS.—Mr. Watson Dyson, Longsight, Manchester, left £50,383. On the decease of his wife he bequeathed £500 to the Manchester and Salford Hospital for Skin Diseases, £500 to the Little Sisters of the Poor for charitable works, and the ultimate residue of his property to be divided into 12 parts, of which three go to the Manchester Royal Infirmary for an Anna Marie bed, to be named after his wife, three to the Ancoats Hospital and Ardwick and Ancoats Dispensary for a similar bed, one part to St. Mary's Hospitals, one part to the Crippled Children's Help Society, one part to the Manchester Royal Eye Hospital, and one part to the Salvation Army.—Mrs. Constance Armstrong left the greater part of her estate to be distributed to hospitals and institutions, and the trustees have allocated, amongst others, the following amounts: £1600 each to the Cancer Hospital, Fulham-road, London; Cancer Charity, Middlesex Hospital, London; Liverpool Hospital for Cancer and Skin Diseases; the Caird Cancer Wards, Dundee Royal Infirmary; the Imperial Cancer Research Fund, London; for cancer cases at the Royal South Hants and Southampton Hospital. £1500 for cancer cases at the Royal Victoria and West Hants Hospital, Boscombe; £1200 to the Royal National Lifeboat Institution; £500 to the Samaritan Free Hospital for Women and Children, Marylebone-road, London.—Under the will of the late Mr. William Shepherd the following payments have been made: £35,000 to Guy's Hospital to finance the erection and completion of the new massage department and extension of the Nurses' Home; £25,000 to the Bolingbroke Hospital for the erection and completion of a wing; £20,000 to St. Thomas's Hospital for the erection of dining and recreation rooms for the use of the nurses; and £6000 to the Belgrave Hospital for Children, Clapham-road, for the purpose of continuing the erection and completion of the south wing. Sums of £1000 have been received by the following hospitals for the endowment of beds: The City of London Hospital for Diseases of the Chest; the Middlesex Hospital; the Hampstead Hospital; the Charing Cross Hospital; St. Mary's Hospital; St. George's Hospital; Evelina Hospital for Children; the Miller General Hospital; the Royal Free Hospital; the Westminster Hospital; and £500 to St. Monica's Hospital.

THE Wellcome Historical Medical Museum, at 54A, Wigmore-street, London, W., will be closed for cleaning and decoration from April 1st to 30th inclusive.

THE Thirty-fifth Congress for Internal Medicine will take place in Vienna, under the chairmanship of Prof. K. F. Wenckebach, from April 9th to 12th, as we have already announced, the chief subjects to be discussed being Encephalitis Lethargica and the Consequences of Increased Arterial Pressure. Information with regard to the journey can be obtained from the Austrian Legation, 18, Belgrave-square, London, S.W.1.

ROYAL MICROSCOPICAL SOCIETY.—The section of the Society which has been formed to deal with the Industrial Applications of the Microscope will hold a meeting at 20, Hanover-square, London, W., on Wednesday, March 28th, at 7 P.M., when a number of important exhibits in microscopic construction and technique will be made.

SOCIETY FOR THE STUDY OF INEBRIETY.—The annual meeting will be held in the rooms of the Medical Society of London, 11, Chandos-street, Cavendish-square, London, W., on April 10th, at 4 P.M., when Dr. W. M. Feldman will open a discussion on Racial Aspects of Alcoholism.

NATIONAL COLLEGE OF TEACHERS OF THE DEAF.—The annual general meeting of the National College of Teachers of the Deaf was held at the Bonnington Hotel, W.C., on Saturday, March 17th, Mr. Sibley Haycock, chairman of the College, presiding. The annual report for 1922 was passed, when Lord Charnwood, the President of the College in succession to Lord Sheffield, and Dr. Eichholz, chief medical inspector of the Board of Education, delivered addresses to an interested audience. The President spoke warmly of the great work which had been done by the College as evidenced by the able records published in the *Teacher of the Deaf*, under the editorship of Mr. A. J. Story; while Dr. Eichholz was able to congratulate the teachers on the fact that the break in all educational development during the war bade fair to be made up, when further progress could be expected along their own special lines. In a very interesting address he indicated how frequently educational departures had had their origin in the procedure of the teachers of the deaf.

Obituary.

SIR WILLIAM THORBURN, K.B.E., C.B., C.M.G., M.D. MALTA (HON. CAUSA), M.D., B.S., B.SC. LOND., F.R.C.S. ENG.,

EMERITUS PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF MANCHESTER.

BY the death, while still at middle age, of Sir William Thorburn, which took place on March 18th at his London residence, York Gate, Regent's Park, British surgery suffers a real loss. Although particularly well known for work upon the surgical treatment of diseases and injuries of the spinal cord, where his researches had brought the Manchester school to the very front, he was generally a great investigator as well as a practical operator. His far-sighted studies of the lesions provided by trauma have illuminated many difficult places in diagnosis.

William Thorburn, the son of John Thorburn, professor of obstetric medicine at Owens College, Manchester, and physician to the Manchester Royal Infirmary, was born in Manchester on April 7th, 1861, and was educated at the College and at the Infirmary, completing his early professional studies in London. After graduating B.Sc. in 1880, he proceeded to the M.B., B.S. in 1884 with distinction, obtaining the scholarship and gold medal for obstetric medicine, and the gold medal in surgery. A year later he took the M.D., and in 1886 became F.R.C.S. Eng. His father had just died, leaving his "Treatise on Diseases of Women" in the press, and Thorburn's first literary work was the bringing out of his father's books. After qualification he became house surgeon to Mr. Hardie at the Manchester Royal Infirmary, and so stimulated that rather retiring surgeon that his classes at once became famous. He was afterwards surgical registrar at the Infirmary, and it was during this period that the genius of Dr. James Ross inspired him and instigated him to investigate the distribution on the body of the various spinal sensory roots. His first articles, dealing with the cervical roots, were published in *Brain* (January, 1887, and October, 1888). Subsequently, in the *Medical Chronicle* (April, 1889), he dealt with the lumbo-sacral roots and first described the anæsthetic "saddle-shaped" area on the buttocks and thighs caused by lesions of the lowest part of the spinal cord and its roots. In June, 1889 (*Medical Chronicle*), a tumour of the cauda equina was investigated by him confirming his previous views. Subsequently, as years went by and clinical opportunities arose (for he never did animal experiments), he was able to map out the whole body in its sensory areas proper to each sensory root. Although slight correcting modifications in these areas have been made by others, yet Thorburn's work on this all-important part of neurology was not only pioneer work, but was a complete work.

Thorburn had already ventured a prediction which his own investigations and successful operations did much to verify—viz., "that acting under strict antiseptic precautions and aided by modern knowledge, surgeons will probably, in the near future, open the spinal canal with as little danger and as little hesitation as they now operate upon the cavity of the cranium." All of which has come to pass, but under the proviso laid down by Thorburn that the accuracy of our diagnostic methods be increased. This contribution to the surgery of the spinal cord is a striking landmark in progress and may be still consulted with advantage both by the surgeon and the physiologist. Very early also Thorburn investigated the nervous symptoms following accidents of various kinds—what was called "traumatic hysteria," especially in relation to railway accidents—and in which no organic changes had been produced or were observable. The terms "railway spine" and "concussed spine" were then common, but are now assessed at their true clinical value. This early work of three decades ago led directly to his great life work, and eventuated in his reaching most worthily one of the highest positions as a sagacious, reliable, and successful surgeon. Thorburn's knowledge of the work on these then obscure diseases led to his being largely consulted by the leading railway companies, and his opinions and judicial pronouncements were held in high esteem.

As Hunterian Professor he delivered at the Royal College of Surgeons of England in 1894 a series of lectures on spinal injuries, dealing in a masterly manner with the anatomy and physiology of his subject, and paying special attention to the differentiation of the spinal segments; and in December of last year, nearly 30 years after the delivery of these lectures, he summed up in the Bradshaw Lecture his subsequent operative experience and the modifications in his views which that experience had led him to adopt. Although he himself took a somewhat gloomy view of the results of his labours—regretting that he had never had the advantage of working in a special hospital—he was able to point to a number of cases in which life had been saved or prolonged, and in which much suffering had been averted. He was a contributor to Burghard's "System of Operative Surgery," and in 1906 published a "Course of Instruction in Operative Surgery."

A deputy lieutenant for co. Lancaster Thorburn had been a Member of the Council and Court of Examiners of the Royal College of Surgeons of England, a Member of the Court and Council of the Victoria University of Manchester, where he was professor of clinical surgery and honorary surgeon to the Manchester Royal Infirmary. In 1913 he was one of the hon. secretaries of the section of surgery at the Thirteenth International Congress of Medicine in London. On the outbreak of war he held the rank of Lieutenant-Colonel R.A.M.C. (T.), and he was at once placed in command of the 2nd General Western Hospital, afterwards becoming consulting surgeon to the British Armies in Malta, Gallipoli, Salonika, and France, successively, with the rank of Colonel A.M.S. He was mentioned in despatches, and for his services was awarded a C.B. in 1916, and a C.M.G. and a K.B.E., military, in 1919. He also received the honorary M.D. of the Malta University.

"With such a full life," writes a friend and colleague, "little time was left for recreation. He was fond of foreign travel when circumstances permitted, especially of a sea voyage, and he was a clubman and a noted whist player; in his early years he was a most ardent volunteer, holding a commission in the 4th Volunteer Battalion, Manchester Regiment, and he raised the Owens College Company (now the Manchester University O.T.C.). He was years ago a member of a very select Manchester tactical society, and a noted player of the 'war game.' For outdoor sports he was never an adept, and therefore never followed them up seriously. He was a most brilliant speaker and clear and deliberate writer and thinker, he mapped out his course long beforehand and generally attained the high pinnacle he had looked forward to. Anything he undertook was thoroughly done and on committees it was always his voice that settled affairs, and on small committees he generally became the perfect committee of one. Although apparently a most cool, calm, and deliberate man, he was instinctively a nervous subject; his cool manner was in the first instance assumed to hide his nervousness. In later years it became rather a pose and sometimes this, combined occasionally with a slight superciliousness, rather repelled some people, but only those who did not know him. For he was straight in all his dealings and trustworthy as a rock."

Sir William Thorburn's home life was marred by tragedy. His three sons were all killed abroad, the last of them at Gallipoli in 1915. He married Miss Augusta Melland, of Manchester, in 1890, and she died unexpectedly and with startling suddenness in 1922. He leaves three daughters.

DR. LUCIUS SPENGLER,

CHEF-ARZT OF THE SANATORIUM SCHATZALP.

WE announced last week the death of Dr. L. Spengler at Davos, giving some indication of his life work. Born on Oct. 8th, 1858, to Alexander Spengler and Elisabeth Ambühl, his wife, he received, as the first born, the traditional Grisons name of Lucius. He attended the local school, going on to the cantonal school in Chur, and from there to the Universities of Zürich, Tübingen, and Heidelberg, returning to Zürich to assist Krönlein and Wyss. In 1887 he went back to Davos-Platz to practise, and in the following year married Helene Holsboer, who bore him five children, and was an admirable life companion. His intention to take up general practice gradually gave way to the recognition which he soon gained as a diagnostician in pulmonary disease. He was in the habit of keeping exact notes of all his cases which in the course of an active life numbered some 12,000; patients came to him from all parts of the world on the report of others that they had found in him a sure guide for the period of their "cure" and a wise adviser for their future life and activities. Many young colleagues whom he trained as assistants gained something of his own precise method and clear vision. He welcomed with keen interest any new addition to the therapy of tuberculosis, nevertheless retaining his critical detachment of judgment. The sanatorium on the Schatzalp, one of the most beautiful sites in Europe, was built to his own specification with the help and technical advice of his father-in-law, W. J. Holsboer. It was there that with the assistance of Dr. Ed. Neumann, who became his brother-in-law, he accumulated a large experience of the results of sanatorium treatment in the Alps.

Parliamentary Intelligence.

HOUSE OF COMMONS.

FRIDAY, MARCH 9TH.

Cost of Pensions Administration.

Sir JOHN COLLIE asked the Minister of Pensions what was the total expected annual cost of the administration of the current year of the Ministry of Pensions, divided into general, medical, and local war pensions committees; what number of pensions, exclusive of widows, children, and dependents, were receiving disability pensions on August 1st, 1921, and on Feb. 1st, 1922; what was the annual cost thereof, respectively; what was the annual expenditure incurred in respect of the medical boards for examining disabled pensioners; what was the amount of the salaries and fees paid, respectively, to whole-time medical officers and part-time medical officers engaged on this duty; how many whole-time medical officers were employed by the Ministry on August 1st, 1921, and on Feb. 1st, 1922, respectively, and how many of these were engaged at institutions; how many disabled men who were in receipt of disability pensions on August 1st, 1921, had now ceased to draw pensions by reason of death, being settled by gratuity, or a final weekly allowance in lieu of pension, and of their disability having become less than 20 per cent.; how many disabled men were in receipt of disability pensions of 20 per cent. and 30 per cent. during the year ending Feb. 1st, 1922; how many three-men medical boards were now employed by the Ministry of Pensions; and what was the saving brought about by the substitution of two-men to three-men boards.—Major TRYON replied: The estimated total cost of administration of my department (including committees) for the financial year ending March 31st is £4,180,000, of which £1,110,000 is for medical services. The cost of sessional fees for boarding during the current financial year is estimated at £450,000. Salaries of medical officers cannot readily be apportioned as between boarding and treatment duties. The number of whole-time medical officers employed on the dates mentioned were 632 and 605, of whom 315 and 289 respectively were at institutions. The number of medical boards of any kind naturally varies from day to day according to requirements, but the average number of three-men boards is about 170 a day. All cases coming up for re-survey are now examined by two-men boards, a change which effects a considerable economy. The statistics asked for in the second, third, seventh and eighth parts of the question are not available for the dates mentioned, without considerable research, but I am sending the hon. Member copies of the last two annual reports of my department, which will, I trust, provide him with information sufficient for his purpose

WEDNESDAY, MARCH 14TH.

Pensions Administration.

Mr. F. ROBERTS moved: "That an humble Address be presented to His Majesty praying that the Regulations dated Jan. 23rd, 1923, made by the Minister of Pensions under the War Pensions Act, 1921, entitled the War Pensions Committee (General) Regulations, 1923, be annulled." He said that Regulations like those now under review did not seem to him to be capable of bringing to an end a most unsatisfactory position in connexion with hundreds of pension cases. If these Regulations followed on those which had already been operating it seemed to him that they were bound to lead to further chaos of administration. They would force large numbers of disabled men into periods of misery, both of body and of mind; they would prevent widows from securing justice, and they would deprive the orphans of fallen soldiers of that subsistence allowance which was their due. They might even cause many more to be added to the list of those unfortunate fellows who had to have recourse to Poor-law assistance and other sheltering institutions as a result of losing their reason through war service.—Mr. LAWSON seconded.

Major TRYON (Minister of Pensions), in resisting the motion, said that if it were carried every object for which the hon. Members had spoken would be defeated. The work would go on, but it would mean that the setting up of voluntary committees would be stopped and the whole of the new area system would be deprived of the advantages of the voluntary committee. What they wanted was more voluntary workers. He was glad to say that people were coming in very well. These Regulations did not limit anything that the ex-Service men might get. If they were not passed all that would result would be difficulties and delay in the work of the Ministry.

After considerable discussion the motion was rejected by 143 votes to 105.

Mr. ROBERTS further moved: "That an humble Address be presented to His Majesty praying that the provisional Regulations dated Feb. 2nd, 1923, made by the Minister of Pensions under the War Pensions Act, 1921, entitled the War Pensions (Final Awards) Amendment Regulations, 1923, be annulled." He particularly objected to the Regulation that when an officer or man had refused to undergo treatment certified to be necessary in his interest regard should be had to what would have been the probable condition of his disability had he undergone such treatment. It seemed to him an unwarrantable proposal that if a man came to the conclusion that the treatment offered him was not acceptable to him he was likely to be deprived of his pension.—Mr. LAWSON seconded.

Major TRYON said he understood that no difficulty would ever be made in regard to pensions in the event of a man exercising the natural right which everybody had to refuse a major operation, but he was told that in some cases where a very simple thing would have enabled a man to use a hand, the pensioner would not have that small operation performed. He agreed that this was a provision which should be used with care, and that it should only be applied in exceptional circumstances.

Mr. ROBERTS: Who would be the deciding authority in this case?—Major TRYON: It would naturally be a medical opinion.

Mr. ROBERTS: Would it be a medical opinion given through the Ministry of Pensions?—Major TRYON: Naturally; but we would take other opinions into consideration. Proceeding, the right hon. gentleman said that the points which they were seeking to achieve by these regulations were two. First of all they gave rights of appeal on final awards to the pensioners; and secondly, they were taking power to make the assessment not 10 per cent. of the time, but 5 per cent. of the time, which gave an advantage to the man when he was suffering from total disablement. He hoped the House would support him in pushing on with the final awards.

The motion was rejected by 134 to 93.

Reigate and Redhill Hospital.

Mr. EDE asked the Minister of Health if he was aware that it was proposed to spend £30,000 in alterations to the Reigate and Redhill Hospital, which was built on a cramped and unsuitable site; whether the Surrey Voluntary Hospitals Committee, of which the Lord Chancellor was chairman, had given careful consideration to the proposal and had advised the hospital authorities not to proceed on the present site; and whether, in view of the urgent need for a modern, well-equipped hospital to serve the south-eastern area of Surrey, and especially having regard to the fact that a suitable and commodious site had been presented to the hospital committee, he would endeavour, by conference with all the parties concerned or otherwise, to persuade the hospital committee to reconsider its decision.—Mr. N. CHAMBERLAIN replied: I understand that the Voluntary Hospitals Commission have not received any communication on this matter from the Surrey Committee of which the hon. Member is a member, but I have asked that the question should be brought to the notice of his colleagues on that committee.

Houses not Fit for Habitation.

Mr. TREVELYAN THOMSON asked the Minister of Health how many towns had reported surveys made of houses not reasonably fit for human habitation; how many houses had been so condemned by medical officers of health and local authorities; and the total population covered by these reports.—Mr. NEVILLE CHAMBERLAIN replied: Reports from medical officers of health for 1060 boroughs and urban districts for the year 1921 show that 994,005 houses were inspected under the Public Health Acts and Housing (Inspection of Districts) Regulations; 13,279 houses were reported as unfit for habitation, and 226,713 as not in all respects reasonably fit. Notices under Section 28 of the Housing Act, 1919, were served in respect of 30,818 houses, and of these 23,453 were rendered fit by the owners and 912 by the local authorities. Notices were served under the Public Health Acts in respect of 266,549 houses; in 240,310 of the houses concerned the defects were remedied by the owners and in 2757 by the local authorities. Defects were remedied in 223,546 houses without the service of formal notices. Closing orders were made in respect of 1416 houses, while in the case of 287 houses closing orders were determined after the houses had been made fit. There is no information regarding the population inhabiting these houses.

Diagnosis of Small-pox.

Mr. FRANK LEE asked the Minister of Health the methods adopted by the medical inspectors of his department in order to decide whether cases of illness examined by them were small-pox or not; and whether the vaccinal condition of the patients was taken into account as one of the factors to decide the diagnosis—Mr. N. CHAMBERLAIN replied: The medical officers of the Ministry who advise in regard to the diagnosis of suspected cases of small-pox are those who have had considerable experience of that disease, and in forming an opinion as to the nature of the illness they take into account all known factors, including the vaccinal condition of the patients.

Successful Vaccination.

Mr. HAYDAY asked the Minister of Health what were the external evidences of a successful vaccination; what steps were taken by his department to ascertain that public vaccinations were successful; and whether he could give any guarantee as to the length of time vaccination continued to remain successful.—Mr. N. CHAMBERLAIN replied: I am advised that the external evidence of successful vaccination is the production at the seat of inoculation of the characteristic and well-defined marks. As regards the second part of the question, the work of public vaccinators is periodically inspected by medical officers of my department in order to secure that a high standard of public vaccination is attained. As regards the third part, the Royal Commission on Vaccination stated that the protection vaccination affords against attacks of small-pox is greatest during the years immediately succeeding the operation of vaccination; that it is impossible to fix with precision the length of this period; and that, though not in all cases the same, if a period was to be fixed, they thought it might fairly be said to cover in general a period of nine or ten years.

Medicines for Panel Patients.

Sir WILFRID SUGDEN asked the Minister of Health what steps were being taken to ensure fit and proper medicines being supplied to panel patients where the price of such medicines was higher than the sums allowed in the contract.—Mr. N. CHAMBERLAIN replied: The hon. Member is under a misapprehension. The cost of the medicines to which persons insured under the National Health Insurance Acts are entitled are not subject to any such limit as is suggested in the question. Insurance practitioners are required to order for their patients such medicines as are required for their proper treatment without limit of price, though it has been found necessary to take certain precautions against extravagance in prescribing.

Small-pox in Derbyshire.

Mr. FRANK LEE asked the Minister of Health whether the official from his department who went into Derbyshire to investigate the outbreak of small-pox had made his report; whether such report was available to Members; and whether the suggestion of the district council that there should be an isolation of contacts was being accepted.—Mr. N. CHAMBERLAIN replied: The answer to the first part of the question is in the affirmative. These reports are intended to be confidential, and, as at present advised, I do not propose to publish the reports made by medical officers of the department in regard to this outbreak. As regards the last part of the question, I am advised that isolation of the contacts of a case of small-pox is not generally necessary either in the interests of the contacts or for the protection of the public, unless and until the contacts themselves develop the disease.

Certified and Non-Certified Deaths.

Mr. SNELL asked the Minister of Health if he could give, for each of the five years 1918 to 1922, the number of deaths registered on a certificate of a registered medical practitioner; the number registered on a coroner's certificate after inquest; and the number of uncertified deaths on which no inquest was held.—Mr. N. CHAMBERLAIN replied: The table gives the information required:—

Year.	Deaths registered.			
	On medical certificate.	On coroner's certificate.	Uncertified.	Total.
1918	570,735	33,013	8,244	611,991
1919	466,068	31,488	6,698	504,254
1920	429,456	31,011	5,663	466,130
1921	424,166	29,304	5,240	458,710
1922	450,996	30,346	5,487	486,829

Medical Classification and Pension Awards.

Sir EDWIN STOCKTON asked the Minister of Pensions whether, in consideration of claims for maladies alleged to have a war-service origin, the Ministry took into consideration and accepted at its face value the fact that the applicant was, after medical examination, passed into the Army classed as A 1.—Major TRYON replied: The man's medical classification on enlistment, along with all other facts of the case, is fully considered in dealing with any claim to pension.

Pensioners in Mental Hospitals.

Mr. GILBERT asked the Minister of Pensions whether any pensioners under the charge of his department were at present patients in any of the London County Council mental hospitals; if he could state, approximately, what number of patients there were; what arrangements were made for payment; if any part of the men's pensions were deducted towards the cost of hospital maintenance; and what amount.—Major TRYON replied: There are approximately 800 Service patients in the mental hospitals of the London County Council. Payment for the cost of their maintenance and treatment is made by my department direct to the medical superintendents of the hospitals. During treatment pension is suspended and the allowances authorised by Article 6 of the Royal Warrant are granted.

Women's Deaths from Illegal Operations.

Mr. BURGESS asked the Minister of Health the number of women whose deaths were attributed to illegal operations during the years 1914 and 1922, respectively.—Mr. BRIDGEMAN (Home Secretary) replied: Figures are not yet available for the year 1922. In some cases in 1914 it was not clear, on the information given, by what means abortion had been procured, and accordingly the numbers are given of all cases of death classified under the heading, "Attempt to procure abortion"—namely, in 1914, 35; and in 1921, 41.

THURSDAY, MARCH 15TH.

Army Medical Services.

The House went into Committee on a Vote on Account for a sum not exceeding £20,000,000 for Army Services during 1923–24, Captain FITZROY in the chair.

Lieut.-Colonel FREMANTLE, in calling attention to the Army Medical Services, said that those services were liable to be forgotten. He was glad to see that there was a slight increase in the Army Dental Corps, which was very vital for the purposes of the army. Those who had served as medical officers during the war knew what a fruitful source of invaliding and inefficiency was the absence of proper dentures. It was a great grievance that those dental surgeons who served in the army during the war and had agreed to remain in the service permanently should lose their gratuity. The contract medical officers were allowed to retain their gratuity when they accepted permanent service. The British Dental Association had gone to the War Office and the Army Council repudiated the agreement made under Instruction 131 and refused to refund the gratuity. The Army Medical Corps of the Territorial Army was a very difficult subject. The original idea was that they should keep up the cadres of all the different units so that in the event of war, as in the case of the scheme initiated by Lord Haldane, there could be complete expansion. It was neglected under Lord Kitchener. One of the chief requirements for expansion in regard to the medical service were the needs of the big general hospitals. They needed to have the establishments kept up in peace time so that in case of war they might get to work at once. This could be done without undue expense by having the nucleus of these units which was the general hospital. They had been cut down. There was one general hospital for each Territorial Division, and that provision had been cut down. Instead of 14 general hospitals there were now only three, one in London, one in Edinburgh, and one in Manchester. In the rest of the country the doctors had no experience of the organisation of a general hospital. It would be infinitely better to have the cadres of 10 big general hospitals in the big centres in order that a fresh set of young medical officers might have training in the organisation and running of a hospital than to have three large hospitals in three large towns. Since the South African War the Royal Army Medical Corps had held a very high position, in fact, the premier position among the medical services of the Crown, and it had proved its worth during the Great War. But when the last examination was held for 15 vacancies in the Corps, there were only four applications. One was not qualified, and only three passed the test. All four were given commissions and the remaining 11 commissions were left vacant. He did not understand the falling off in the popularity of the Corps. In the case of the technical professions they had to remember that the Government had to compete with civil practice, and there must be comparable terms and conditions. He imagined that some of the conditions in the R.A.M.C. did not correspond sufficiently well with the prospects in civil life, and that was one of the results of economy. The Corps must be saved. He knew the difficulties, but he said that health was so vital all the way through the activities and organisation of the army that the only way they could prevent the constant trouble, loss of life, and lack of coördination they had had at the beginning of every war, was to organise properly and give the Director-General of the Army Medical Service a seat on the Army Council. He believed that a Cabinet Committee, under Sir A. Mond, reported some time last summer on the subject of the medical services and how far it was possible to get union, fusion, or coöperation between the medical services of the three fighting services. He asked once more whether that report could be published because it would be invaluable.

Lieut.-Colonel GUINNESS (Under-Secretary for War), replying to the debate, said his answer to Colonel Fremantle was that members of the Army Council had never sat as representing particular groups or kinds of soldiers, but as representing groups of functions. If they adopted that view they should surely discourage the separation of the army into water-tight compartments. If they were going to give representation to the Territorial Army and the Royal Army Medical Corps they would have the same claim for the Royal Engineers.

Colonel FREMANTLE said that was just the mistake that was constantly being made and contended against. The desire and recommendation of the Committee in 1902, and again of Lord Esher when he wrote to the *Times*, was that the Director-General of the Royal Army Medical Corps should be on the Army Council to represent the health services in the army.

Colonel GUINNESS said he quite realised that a good many people held the contrary view, but he suggested that all these matters could best be considered by such a Committee as that of Lord Weir, which was going into the whole of the establishment and the organisation which controlled it.

The Vote was agreed to.

Water-supplies of the Country.

Mr. GRAHAM WHITE asked the Minister of Health if he would institute an inquiry into the sources of water-supplies of this country, having regard to the future needs of an increasing population, and with a view to the elimination of competition between local authorities in respect of available sources of supply.—Mr. N. CHAMBERLAIN replied: Such an inquiry is now being undertaken by my department.

The New Housing Bill.

Sir KINGSLEY WOOD asked the Prime Minister whether there was any likelihood of the Government's housing proposals being announced before Easter.—Mr. BONAR LAW replied: It is unlikely that it will be possible to make an announcement before Easter.

MONDAY, MARCH 19TH.

Refuse Nuisance in Outer London Area.

Sir CYRIL COBB asked the Minister of Health whether he was aware that parts of the outer circle of the London area were being made dumping-grounds for the refuse of the various borough councils situated within the administrative area of the county; and whether, in view of the consequent danger to health in connexion with the new housing estates which were developing there, he would say if his department was taking any action to check this practice and enforce on the borough councils some other and better method of disposing of their refuse.—Mr. NEVILLE CHAMBERLAIN replied: I am aware that complaints have been made as to the nuisance created by the establishment of refuse tips in the outer parts of the London area. Last July my department issued a circular to local authorities on this subject, specifying a number of precautions to be taken, and I am assured that since that date a considerable improvement has taken place. Owing to the high capital cost of alternative methods I do not consider it practicable to enforce them upon borough councils by legislation, but in my opinion it is highly desirable that where possible modern methods of dealing with town refuse should be adopted.

Silicosis among Miners.

Mr. WILLIAM JENKINS asked the Secretary of State for the Home Department whether he was aware that a number of workmen who were employed in the coal-mines were boring in hard ground and were certified by medical experts as suffering from silicosis due to dust; whether he was aware that there was no provision for the men to claim compensation; and would he include them in the schedule of industrial diseases.—Mr. BRIDGEMAN replied: I have no information as to the cases referred to in the question, but I shall be glad to consider, in consultation with the Mines Department, any particulars the hon. Member is able to send me.

Standardisation of Serums and Vaccines.

Mr. LANSBURY asked the Minister of Health whether the conferences of bacteriologists called by the League of Nations Health Committee in London and Paris to discuss the standardisation of serums and vaccines were paid for by the Governments represented; whether the representatives received any remuneration in addition to the expenses incurred in travelling from all parts of the world; and, if so, what was the amount respectively in expenses and in remuneration paid by the British Government, who were our representatives, under what votes were such items authorised, and where did they appear in the accounts.—Mr. NEVILLE CHAMBERLAIN replied: The expenses of the conferences on the standardisation of serums held in London in December, 1921, and in Paris in November, 1922, which consisted mainly of the travelling and subsistence allowance of the delegates, were met from the funds of the League of Nations. No fees or other remuneration were paid to delegates by the

British Government. Indeed, I am not aware that any expense was incurred from public funds beyond the cost of luncheon for the foreign delegates provided by the Government hospitality fund on the occasion of the conference in London.

TUESDAY, MARCH 20TH.

Women Health Inspectors.

Mr. JAMES BUTLER asked the Minister of Health what were the duties of the women general inspectors of the Ministry of Health; what was the number of Poor-law institutions in England and Wales; and what number were inspected by women inspectors last year.—Mr. NEVILLE CHAMBERLAIN replied: The duties of the women general inspectors of the Ministry of Health comprise the routine inspection of Poor-law infirmaries, sick wards and nurseries, of Poor-law institutions, and also of children's homes and boarded-out children. The number of Poor-law institutions in England and Wales is 722, to which 206 visits were paid by women inspectors last year.

Local Authorities Expenditure.

Mr. LEACH asked the Minister of Health what was the total amount of expenditure of all the local authorities of the Kingdom for the last year of which he had now returns; and the total Exchequer grants to the same authorities for the same year.—Mr. NEVILLE CHAMBERLAIN replied: The total expenditure from the rates by local authorities in England and Wales for the year 1920–21 was approximately £152,000,000, while the Exchequer grants for the same year amounted to £63,000,000.

Silicosis among Miners.

Mr. WILLIAM JENKINS asked the Secretary of State for the Home Department whether he was aware that a large number of miners were suffering from lung trouble due to the effect of working in dusty mines; and whether he would take steps to include such in the schedule of industrial diseases.—Mr. BRIDGEMAN replied: If the hon. Member is referring to cases of silicosis, I have no evidence before me to show that this is so, except in the case of one or two special classes such as ganister miners. A scheme of compensation under the Workmen's Compensation (Silicosis) Act is already in operation for men engaged in getting mineral for use in the refractories industries. As regards other diseases, such as bronchitis and pneumonia, the health statistics show that miners are more susceptible to some respiratory diseases than the general population and less susceptible to others. The experience, however, differs with different classes of miners. The Industrial Diseases Committee considered the question of scheduling such diseases under the Compensation Act, but they reported that while they thought it probable that the ailments often had an industrial origin among workers exposed to dust or fumes, there was no means of distinguishing such cases from ordinary cases of disease, and they were unable to advise their inclusion.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

SOCIETIES.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MEETINGS OF SECTIONS.

Monday, March 26th.

ODONTOLOGY: at 8 P.M.
Casual Communication:
Mr. J. Howard Mummery and Mr. B. Grellier: Multiple Dentigerous Cysts.
Paper:
Mrs. Mellanby: Diet, Dental Structure and Caries.

Tuesday, March 27th

MEDICINE: at 5 P.M., *at St. Bartholomew's Hospital, E.C. 1.* Tea will be provided at 4.30 P.M.

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, March 26th.—9 P.M., Third Lettsomian Lecture. Mr. W. E. Miles: Carcinoma of the Rectum.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST END HOSPITAL FOR NERVOUS DISEASES.

The following Clinical Demonstrations will be held during the forthcoming week in the Out-patient Department of the Hospital, 73, Welbeck-street, W. The Demonstrations are open to Practitioners and Medical Students without fee.

TUESDAY, March 27th.—5 P.M., Dr. Ridley Prentice: Hemiplegia.

C. WORSTER-DROUGHT, M.D., Dean.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

MONDAY, March 26th.—10 A.M., Mr. MacDonald: Genito-Urinary Dept. 12 noon, Mr. Addison: Surgical Wards. 3 P.M., Mr. Simson: Diseases of Women.

TUESDAY.—10 A.M., Dr. Drummond Robinson: Gynæcological Operations. 12 noon, Dr. Burrell: Chest Cases. 2.30 P.M., Mr. Tyrrell Gray: Surgical Wards.

WEDNESDAY.—10 A.M., Dr. Saunders: Medical Diseases of Children. 11 A.M., Mr. Simson: Gynæcological Demonstration. 2.30 P.M., Mr. Donald Armour: Surgical Wards.

THURSDAY.—12 noon, Mr. Simmonds: Demonstration of Fractures. 2 P.M., Mr. Bishop Harman: Eye Dept. 3 P.M., Dr. Scott Pinchin: Medical Cases.

Daily, 10 A.M. to 6 P.M., Saturdays, 10 A.M. to 1 P.M. In-patients, Out-patients, Operations, Special Departments.

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.

THURSDAY, March 29th.—5 P.M., Mr. A. W. Bourne: Prognosis and Treatment of Eclampsia.

MANCHESTER ROYAL INFIRMARY POST-GRADUATE COURSES.

TUESDAY, March 27th.—4.15 P.M., Dr. J. Shaw Dunn: The Kidney and Nephritis.

Appointments.

BURNS, C. W., M.B., Ch.B. Edin., has been appointed House Surgeon at the Ayr County Hospital.

DOWN, E. MONICA, M.B., B.S. Lond., Junior Resident Medical Officer at the Children's Hospital, Sunderland.

INGRAM, F. T., M.B., Ch.B. Edin., House Physician to the Royal Infirmary, Sunderland.

Salford Royal Hospital: DUTHIE, O. M., M.B., Ch.B. Manch., House Physician; BROMAN, B., M.R.C.S., L.R.C.P. Lond., and WILSON, A. J., M.B., Ch.B. Edin., House Surgeons; WALKER, W., M.B., Ch.B. Glasg., Casualty House Surgeon.

Surgeons under the Factory and Workshop Acts: MCARTHUR, W. G., M.B., Ch.B. Aberd. (Thirsk); PEGUM, J. S., F.R.C.S. Irel., L.R.C.P. Irel., (Gravesend); ROBERTSON, R., M.D. Edin. (Ventnor); HUNTER, D. M., M.B., Ch.B. Glasg. (Knighton, Radnor).

Vacancies.

For further information refer to the advertisement columns.

All Saints Hospital for Genito-Urinary Diseases, Vauxhall Bridge-road, S.W.—Res. H.S. £200.

Bath, Royal Mineral Water Hospital.—Res. M.O. £200.

Bethlem Hospital, Lambeth-road, S.E.—Res. H.P. £100.

Birmingham and Midland Homœopathic Hospital and Dispensary.—Res. H.S. £175.

Birmingham and Midland Hospital for Skin, &c., Diesases.—Asst. Radiologist.

Birmingham Children's Hospital.—Phys. to Out-patients.

Bradford City Maternity and Child Welfare.—Asst. M.O. £500.

Bristol Eye Hospital.—H.S. £150.

Bromsgrove, Worcestershire Mental Hospital, Barnsley Hall.—Second Asst. M.O. £300.

Burnley, Victoria Hospital.—H.S. £200.

Cancer Hospital, Fulham-road, S.W.—Anæsthetist.

Ceylon Medical College.—Professor of Physiology and Reg. £800.

City of London Hospital for Diseases of the Chest, Victoria Park, E.—Half-time M.O. £200.

Coventry and Warwickshire Hospital.—Res. H.P. £200.

East London Hospital for Children and Dispensary for Women, Shadwell, E.—Anæsthetist. £50.

Epsom, Queen Mary's Convalescent Centre.—Jun. M.O. £350.

Epsom, The Manor.—Jun. Asst. M.O. £440.

Gloucestershire Royal Infirmary and Eye Institution.—Surg.

Hospital for Sick Children, Great Ormond-street, W.C.—H.P. £50. Also Surg. Registrar. £300.

Hull Royal Infirmary.—Sen. H.S. £200.

Lagos Town Council.—African Asst. M.O.H. £750.

Lincoln, Lindsey County Council.—Asst. Tub. O. and Asst. School M.O. £500.

Liverpool Open Air Hospital for Children, Leasowe.—Jun. M.O. £250.

Liverpool, Royal Southern Hospital.—Hon. P.

London County Mental Hospital Service.—Seventh Asst. M.O. £440.

London Lock Hospital, 91, Dean-street, W.—H.S.

Maidstone, West Kent General Hospital.—H.S. £220.

Manchester Royal Eye Hospital.—H.S.

Norfolk Education Committee.—Asst. School M.O. £500.

Paddington Green Children's Hospital, W.—H.P. and H.S. Each £150.

Plaistow Fever Hospital.—Second Asst. M.O. £200.

Prince of Wales's General Hospital, Tottenham, N.—H.P. and H.S. Each £150. Jun. H.S. and Jun. H.P. Each £110.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Two H.P.'s. and H.S. Each £100. Also Asst. P. £1 1s. per attendance.
Redhill, Surrey, Royal Earlswood Institution for Mental Defectives.—Jun. Asst. M.O. £250.
Rotherham Hospital.—Jun. H.S. £150.
Royal Free Hospital, Gray's Inn-road, W.C.—Cas. O. £100.
Royal Westminster Ophthalmic Hospital, King William-street, Strand, W.C.—Pathologist and Curator. £50.
Seamen's Hospital Society, Dreadnought Hospital, Greenwich, S.E.—H.S. £150.
Sutton, Surrey, Downs Hospital for Children.—Jun. Asst. M.O. £515.
University College Hospital, Gower-street, W.C.—Hon. Ophthalmic S.
Wakefield, Middleton-in-Wharfedale Sanatorium, near Ilkley.—Res. Asst. M.O. £325.
West End Hospital for Nervous Diseases, 73, Welbeck-street, W.—Hon. Registrar.
Western Australia Lunacy Department.—Jun. A.M.O. £432.
Wigan Infirmary.—Hon. Asst. P.
Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

The Secretary of State for the Home Department gives notice of vacancies for Medical Referees under the Workmen's Compensation Act at Ayr, Berwick, The Lothians, Fife and Kinross, Renfrew, Ross, and Stirling. Applications should reach the Private Secretary, Scottish Office, Whitehall, London, S.W., not later than April 4th.

Births, Marriages, and Deaths.

BIRTHS.

COXON.—On March 9th, at Dersingham, Norfolk, to Ella, the wife of Cedric Coxon, M.B.—a daughter.

FOURACRE.—On March 18th, at Withernsea, East Yorks, the wife of Sidney F. Fouracre, M.B., B.S. Lond. (née Muriel Isaac), of a son.

IRVINE.—On March 11th, 1923, at Abbottabad, N.W.F.P., India, the wife of Major M. L. C. Irvine, Indian Medical Service, of a son. (By cable.)

KINDERSLEY.—On March 15th, at Ulster Lodge, Warminster, the wife of Dr. Charles Kindersley, of a son.

WALSH.—On March 10th, at Douglas-road, Handsworth, the wife of Dr. Newton Walsh, of a daughter.

DEATHS.

ECCLES.—On March 11th, at Hove, Herbert Nisbet Eccles, late Captain, R.A.M.C., aged 39.

POLLARD.—On March 14th, at Torquay, Reginal Pollard, M.B., M.R.C.S., aged 61.

SPENCER.—At the Victoria Hospital for Children, Chelsea, Elfrida (Biddy) Spencer, B.A., M.R.C.S., L.R.C.P.

THORBURN.—On March 18th, at York-gate, Regent's Park, N.W., Sir William Thorburn, K.B.E., C.B., C.M.G., D.L., T.D., F.R.C.S., aged 61.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE INSTITUTES OF MEDICINE AND SURGERY:[1]

AN ADDRESS ON THE NATURE OF LIFE.

BY J. S. HALDANE, M.D. EDIN., LL.D., F.R.S.

IN this paper I wish to discuss the general principles of medicine and surgery, principles derived from observation of living organisms in health and disease and of inorganic phenomena, rather than any special part of the accumulated empirical knowledge which they cement together. In the Scottish universities physiology has long been also called "Institutes of Medicine," a title to which physiologists still cling, although they rightly claim that physiology is based on far more than what has been observed in the course of medical practice; one teacher cannot now combine an adequate knowledge of physiology with more than a meagre knowledge of practical medicine and surgery. Physics, chemistry, mathematics, normal and pathological anatomy, are all used in medicine and surgery; physiology is of very great use, but a knowledge of physiology as at present taught does not occupy in medicine and surgery the position which it would presumably occupy if it represented in any actual sense the institutes of medicine. In former times physiology was regarded as the institutes of medicine because physiology, like practical medicine, deals with the living body, while anatomy or chemistry, for instance, was supposed to deal only with what is inanimate. In the latter half of last century, owing to the mechanistic movement, physiology came to be treated as simply the application of physics and chemistry to the phenomena of life.

Current Physiology and the Old Vitalism.

The failure of physiology to furnish guidance in connexion with the cure of disease and recovery from injury is the reason why physiology is no longer looked upon as the institutes of medicine. The reason for that failure is that physiology throws no light on functional restoration of the delicate machinery of the body, and on the efficacy of medical and surgical interference in bringing about that restoration. The vitalistic physiology of former times had at least something to say about these processes; vitalism has disappeared from official physiology, but I believe that many of those engaged in medical and surgical practice are still vitalists at heart.

The old vitalists assumed the existence of a force independent of physical and chemical influences, but acting upon matter within the living body in such a way as to cause the phenomena of life to fulfil their characteristic course. But in experimental investigation it was invariably found that what was put down to the influence of the vital force depends on the operation of physical and chemical stimuli of some kind—as, for example, the presence, in certain concentrations, of oxygen, of different salts, or various organic substances, or structural distortion. Vitalism, in its old sense, has finally disappeared from physiology.

The Aim of Physiology.

If, however, we ask whether the mechanistic physiology can furnish any better explanation of the phenomena, the answer, to my mind, is emphatically negative. The phenomena of recovery from disease and injuries appear so strange that we are unable to understand them. It is exactly the same with the closely-related phenomena of reproduction. The official present-day view of physiologists is that physiology aims at gradually revealing the mechanism of life—that it aims at investigating the physics and chemistry, and might properly be called biophysics and biochemistry. I do not share this view, and I wish to show, if I can, that the proper, and in the main the actual, aim of physiology is very different, being one which brings it into the closest relation with both the diagnostic and therapeutic sides of practical medicine.

Normal Structure and Activity.

The life of an organism is characterised by the persistence of the details of both structure and activity in which its life is expressed. In the transmission of similar characters from one generation to another the same persistence shows itself, and but for it the classification of organisms would be meaningless. But neither what we call matter nor what we call energy remains identical. Matter in the physical sense is constantly replacing itself in a living organism and in generation after generation of organisms. Similarly, energy in the physical sense is constantly replacing itself. What, then, does the persistence consist in?

---

[1] Abstract of an address to the Middlesex Hospital Medical Society on March 6th, 1923.

The external form of an animal varies greatly with varying posture and different individual peculiarities; but there is an almost endless network of anatomical relationships, practically constant in any particular species, and only varying in points of detail in what we consequently regard as allied species. It is the *relationships* which are persistent. Anatomy has, however, hitherto confined itself almost entirely to relationships of structure only, visible after death. The persistence of activity is not so evident in detail. The physiological activities of an organism are persistent as a whole. The amounts of food consumed, or of air breathed, or of energy liberated, are fairly steady from day to day; nevertheless, physiological activities appear to be more or less spasmodic, periods of rest alternating with periods of activity. This feature at first sight seems to justify the comparison of the living body to a complicated piece of machinery; but medicine has little practical use for such a conception. The activity of every part of the living body is in reality continuous, and the difference between so-called activity and so-called rest is only a relative difference in activity. A muscle, or gland, or nerve fibre at so-called rest is still consuming oxygen and forming carbon dioxide. We have only to cut off its supply of oxygen or of normal blood, and functional and structural changes rapidly ensue. We also realise it through the existence of such phenomena as tone in muscles, or the constant afferent influence of all parts of the afferent nervous system. Not even the bones are ever at physiological rest during life; and of this a surgeon or physician cannot help being aware.

Many-sided Physiological Activities of Living Tissues.

To the eye of a physiologist who is trying to see all sides of the activity of living structure that activity is constant, many-sided, and exquisitely sensitive to changes in environment. For instance, a barely detectible difference in hydrogen-ion concentration of the blood will, according to its direction, either arrest temporarily the action of the respiratory centre or enormously increase it. On the other hand, it is equally evident that the changes of environment to which living structures in the body are exposed are very limited in amount, since the composition of the blood bathing these structures is kept remarkably constant. Every year sees important advances in our knowledge of the regulation of the composition of the blood and of the supreme importance of this regulation.

It seems to me that we are led to a very different conception of life from that of either the mechanistic physiologists or the vitalists. Life is a many-sided activity, including on the one hand the action of the environment in contact with the tissue elements, and on the other the action of the tissue elements themselves. The action of the environment seems to determine both the specific structure and the specific activities of the tissue elements, but the tissue elements at the same time determine the specific nature and action of the environment. We can know nothing of either by itself. In other words, the relationship of what we distinguish as structure, environment, and activity is of the essence of what we are observing.

The Scope of Physiology.

Like anatomy, physiology deals with specific relationships. But whereas anatomy has hitherto confined itself essentially to the specific relationships still discoverable in dead structure, physiology includes the relationships discoverable in connexion with living activity and the environment of structure.

The idea that biology deals with all the persistent relationships observable in connexion with different forms of life, and not merely with anatomical relationships, places the study of life in a different theoretical world from ordinary physics and chemistry. For the present the biological and physical sciences are separate, although it looks to me as if the recent developments of physics and chemistry were forging a connecting link.

The Physiology of Renal Secretion.

Let us glance at the sort of explanation which physiology, or, I should prefer to say, biology, can actually furnish. As an example, take the physiology of renal secretion. For the mechanistic school of physiology the problem of renal secretion has been to discover the physical and chemical mechanism by which urine is secreted. But if the reasoning which I have already placed before you is correct, the question of a mechanism of secretion does not arise, because it is at bottom unmeaning. For a physiologist the real question of renal secretion is the discovery by observation and experiment of the biological relationships involved in each aspect of it—what persistent relation each aspect has to the anatomical structure of the living kidney, to the local composition of the blood as related to the blood flow, blood pressure, and nervous activity, to temperature, concentration of urine in the tubules, and anything else that is found to be related to urinary secretion.

When we look broadly at what is definitely known about renal secretion it is evident that the rate of excretion of any of the characteristic urinary constituents depends, under normal conditions, on excess or deficiency of that constituent in the blood, as compared with what is "normal." These excesses or deficiencies are, however, extremely small; an approximately normal condition of the renal blood is essential to occurrence of secretion. If, for instance, the renal blood is not sufficiently oxygenated, or if it contains some substance harmful to the kidneys, normal secretion ceases, and only what may be called leakage occurs. Renal action may also be abnormally stimulated by diuretic substances. The idea of active maintenance of what is normal in the blood, the kidneys, and the body as a whole, is the key to the physiology of renal secretion—the idea which enables us to predict its variations.

Function of Lungs During Rest.

The same considerations apply to the physiology of nutrition, respiration, circulation, temperature regulation, the nervous system, and every other part of physiology with respect to which a considerable body of knowledge exists. It may be argued that in the case of some organs, at least, the evidence for a mechanical theory of function is complete, for instance, in the lungs during rest at normal atmospheric pressure. The evidence furnished by C. G. Douglas and myself shows that under these conditions oxygen passes into the blood through the alveolar epithelium by diffusion alone, while Krogh has furnished similar evidence as regards the passage of carbon dioxide outwards. The alveolar epithelium has only to be injured slightly by a very small dose of phosgene, or nitrous fumes, or prolonged exposure to pure oxygen, or bacterial infection, to render the rate of diffusion of oxygen inwards so slow that the blood is very imperfectly oxygenated during any muscular exertion, so that a patient's life is in danger from sudden fainting. It is evident, therefore, that a normal diffusion rate depends on the exquisitely fine normal structure of the living epithelium and capillaries. What are the physiological relations on which this normal structure depends? What, too, of the conditions on which a normal relative distribution of air and blood in the alveoli depends? His next case of asthma or bronchitis will suggest this physiological question to the clinician. What about all the physiological relations involved in the extraordinarily delicate regulation of breathing? I confess that when I think of the mechanistic theory of life, only my personal respect for those who have held it, or still hold it, prevents me from regarding it with scorn.

"Biology" Preferable to "Physiology."

The old vitalism brought physiology into some sort of living connexion with the therapeutic sides of medicine and surgery, since it suggested a reason why patients recover and wounds heal, and why therapeutic interference helps or renders possible this process. Vitalism is, however, an impossible creed. The only possible creed, it seems to me, is simply that of the fundamental biological ideas which I have tried to explain. They are drawn from direct observation of the nature of life. It is nature, and not the operation of any supernatural vital force that we are dealing with. But in the case of life, nature appears to us under a different guise from that in which she appears in the case of inorganic phenomena. It is just as natural for life to assert itself in face of disease and injury as for it to be continuously asserting itself in face of the changes of environment to which the living body is normally exposed.

Medicine and surgery are therefore based on biology, and biology represents the institutes of medicine. I have said biology rather than physiology, because the word physiology would seem to exclude both normal and morbid anatomy as well as general biology. But structure, environment, and activity are inseparably united in the conception of life, so that it is impossible to leave out a science dealing with organic structure. Future anatomy will certainly set itself to investigate the physiological relationships which are inseparable from structural manifestations, and anatomy, both normal and morbid, will then be just as much an experimented science as is physiology.

In connexion with disease, injury, and the action of drugs and poisons, physiology passes into pathology and pharmacology, and normal into morbid anatomy. The passage is, however, quite natural, and it is still always with biology that we are dealing. It has been my lot to investigate or come into close contact with various conditions in connexion with which physiology, pathology, and therapeutics meet directly. One of these, to which I may refer for illustration, is defective oxygenation of the blood, whether produced by low atmospheric pressure, low precentages of oxygen in the air, abnormality in the nervous regulation of breathing, bronchitis, emphysema, inflammatory conditions in the lungs, the defects in circulation of heart disease, or the effects of poisons such as carbon monoxide or nitrites, which interfere with the oxygen-carrying power of the blood. In some of these conditions the mere knowledge that the patient is suffering from the effects of want of oxygen, and of how this is produced, suggests a remedy at once. This is, for instance, the case where oxygenated air is continuously administered in bad cases of acute poisoning by lung-irritant gases, or, as Meakins has shown, of pneumonia or capillary bronchitis. A knowledge of the physiology of want of oxygen may also suggest an indirect remedy, as where carbon dioxide or some substance which, like carbon dioxide, produces a slight acidosis, is employed.

Even where no remedy is applied, and the cause of the want of oxygen still remains, the patient will invariably recover more or less completely if his condition is not too serious. A typical case of this is recovery from mountain sickness without the patient returning from the high altitude which has caused the mountain sickness. There will, moreover, be no mountain sickness at all if the altitude is reached by slow enough stages, and this is paralleled by the fact that a patient with chronic emphysema or mitral disease, whose blue lips tells a story of imperfectly oxygenated arterial blood or slowed circulation, may nevertheless be practically free from the symptoms of want of oxygen during rest. We have only to give the organism time and it will surmount the want of oxygen. In this it is only true to the nature of life as I have tried to describe life.

The want of oxygen may, however, have already produced serious damage; and this takes us into the sphere of pathology. A patient who has suffered simply from want of oxygen may not recover at once when the want of oxygen is removed, or may remain comatose and ultimately die. We see this only too often in bad cases of carbon monoxide poisoning or of pneumonia or bronchitis, where acute want of oxygen has been for a considerable time unrelieved. But even where very serious pathological changes have been produced, the patient will, when the want of oxygen is removed, usually recover sooner or later. Here, again, we are only in presence of the "nature" of life. Sir James Mackenzie has recently set an example in the matter of studying carefully the early symptoms of disease so as to find means of controlling it before it has advanced too far. In this I am in full sympathy with him: for in reality he is thus attempting to link up more effectively practical medicine with biology—to rescue medicine from the atmosphere of the dead-house.

It is the nature of life which I have been trying to place before you. The nature of life is the "nature" which Hippocrates first saw clearly and made the basis of his teaching and practice; the "nature" of which the etymology of the word "physiology" ought always to remind us; the "nature" of which the conception has run like a golden thread through the history of scientific medicine. It needs someone far more eloquent than I am to preach the gospel of scientific medicine with scientific biology for its institutes; but I have at least done my best.

THE PROBLEM OF LEPROSY.

In his paper on Recent Advances Towards the Solution of the Leprosy Problem, read on March 16th before the Dominions and Colonies and Indian Sections of the Royal Society of Arts, Sir Leonard Rogers, F.R.S., dealt first with the history of leprosy and then with the general relationship between heavy rainfall and high leprosy incidence, which is most marked in the hot, moist portions of the tropical and subtropical zones—an incidence which, he suggested, was due to the fact that the innumerable insect bites experienced in those zones afforded sites of entry through the skin for lepra bacilli derived from neighbouring lepers. Passing on to the communicability of the disease, he stated that numerous statistical data show that only from 3 to 5 per cent. of healthy persons living in the same house as a leper contract leprosy—a proportion, however, which is still over 100 times as high as the general incidence in India, for example.

Conditions Favouring Infection.

General conditions materially influencing the spread of leprosy were as follows: (1) A low stage of civilisation and hygiene, such as obtained in England during the Middle Ages, and still obtains among the poorer inhabitants of extensive and thickly-populated tropical and subtropical countries; (2) general and sexual promiscuity, so marked during the leprosy endemic in Hawaii and during the Middle Ages; (3) favouring social customs, such as smoking the same pipe or eating out of the same dish; (4) the absence of all fear of lepers, found in Hawaii and many other tropical countries—various cruel customs relating to lepers (e.g., in Central Africa) having been recorded as lessening the spread of the disease; (5) deficient diet, especially fresh food, probably by lowering resistance to infection, appeared to be the sole basis of Hutchinson's fish theory of origin, which is now admitted to be quite untenable; (6) the closing of leper hospitals and cessation of segregation have several times been followed by increase of the disease.

Recent Advances in Treatment.

After discussing the difficulties of methods of segregation, Sir Leonard Rogers went on to describe recent advances in the treatment of leprosy, notably in connexion with chaulmoogra and hydnocarpus oils, including gynocardic acid (the lower-melting-point fatty acids of chaulmoogra oil), sodium gynocardate, and ethyl ester chaulmoograte, and also with soluble preparations of cod-liver oil, soya bean, &c. By injection of one or more of these preparations the leprosy bacilli are gradually destroyed within the tissues and may in time completely disappear, as far as microscopical examinations show, together with all outward signs of the disease: in a few cases steady progress and complete clearing up followed a severe reaction produced by a few intravenous injections, although all treatment was stopped after the reaction appeared, indicating the production in the system of effective resisting powers against the bacillus as a result of the destruction and absorption of very numerous bacilli during the reaction. Thus, an important advance had been made on previous methods of treatment. Sir Leonard Rogers expressed himself as anxious to avoid any exaggerated ideas being formed regarding the newer methods; sufficient time has not yet elapsed to say how many of the apparent cures will prove permanent.

The difficulty of effective segregation of early cases is now being lessened by many more applications for treatment on the part of infected persons in whom the disease is not yet advanced. The following Census data from the British-administered districts in India make clear the fall in the incidence there.

Year.	Population.	Lepers.	Per 1000.
1881	196,895,542	118,953	0·60
1891	221,519,797	110,509	0·50
1901	231,899,507	85,878	0·37
1911	243,933,178	92,433	0·38
1921	247,003,293	85,122	0·34

It appears, however, from the reports that in the first two Censuses a considerable number of the harmless leucoderma cases, which somewhat resembles the early stages of the nerve form of leprosy, and also of syphilis cases were erroneously returned as leprosy.

Present Position of the Problem.

There are probably about half a million lepers in India at the present time, although only 102,000 were returned at the last Census, the deficiency being especially among females, in whom the disease is more easily hidden. Sir Leonard Rogers quoted the following, among others, as important figures from his tables: Europe, 7044 (including in South Russia 1200, the Baltic Provinces 1000, Turkey 600, Crete 1000); Asia, 1,256,877, including India 102,503 (an under-estimate), China 1,000,000 (a rough guess, probably not very far out), Japan 102,585, Indo-China 15,000, Philippines 4000, Siam 14,000, Java 4443, Palestine 600, Ceylon 589, Persia 150. Africa, 525,800, of whom over 500,000 occur in tropical Central Africa (5 to 60 or more per 1000); Egypt 6513, Madagascar 4200, and South Africa with Natal 3640. Thus, Africa, China, Japan, and India include the great majority of the lepers in the world.

South America, together with the West Indies, has 23,784 lepers; North America has comparatively few, the numbers in Mexico being unknown, while those in the United States have been variously estimated between 146 and about 1000, the latter being nearer the truth. Oceania shows some very high rates per 1000, but owing to the small area of the islands, the total number in Sir Leonard Rogers's tables was less than 5000. Australia has very few lepers: the coast districts of tropical and subtropical Queensland, which show the heaviest rainfall of the continent, had 21 isolated lepers in 1913. The tables omitted a number of countries with no available figures, yet they totalled nearly 2,000,000, and if early cases could be included, a total of 3,000,000 would easily be reached.

In conclusion, Sir Leonard Rogers stated that the evidence now appeared to him to warrant a more hopeful outlook on the ancient problem of leprosy. Every important leprosy conference of the past three decades had been almost or quite unanimous in regarding leprosy as a communicable disease, for which isolation of infective cases was the only practical preventive measure, which the experience of Norway conclusively showed to be effective wherever it can be adequately and persistently carried out. Hitherto the want of an effective treatment of the disease has led to the inevitable concealment of the early, not easily recognisable, but infective stages as long as possible, to save the patients from life-long incarceration; but modern researches have greatly improved the effectiveness of the treatment of leprosy and opened a new field of research promising still further advances, and although it is still too early to claim permanent cures, yet a few typical cases treated by Sir Leonard Rogers himself have now remained free from all signs of the disease for at least five years, while the infectivity of the disease is greatly reduced or completely removed in successful cases.

COLONIAL HEALTH REPORTS.

Public Health in Penang.[1]

AT the census taken in April, 1921, the population of George Town, Penang, was found to be 123,187, Chinese numbering 82,602, Indians 19,535, Europeans 1063; and the remainder consisting of Malays, Eurasians, and others. The birth-rate was 30·56 and the crude death-rate also 30·56, but if corrected for non-residents 26·87 per 1000. The birth-rate for Chinese was 31·75, and for Europeans 45·15 per 1000; the corresponding death-rates were 26·79 and 9·4. The infantile mortality, 165 per 1000 births, showed a great improvement on all previous years, the lowest rates previously recorded having been 205 in 1920, and the decennial average 251. This improvement is most encouraging, and testifies to the good work carried on by the sanitary authorities. Among Indians the ratio was 229, and among Chinese 168; for Europeans 62. There was a great decrease in deaths from tetanus (22 per 1000 births, against 60 in 1913 and 56 in 1915, and less than in any of the eight years preceding); but a considerable increase under the heading of convulsions (24 per 1000), compared with 9 in each of the two years preceding, and 13, the highest previous record, in 1917. For the population as a whole, the chief causes of death were phthisis (580) and other tuberculous disease (72), malaria (420), and pneumonia (220); but in each case the mortality was less than the decennial average. Anti-mosquito work has been carried out all over the town, but especially in the suburbs, and with good results. Overcrowding exists in many districts, and particularly in the common lodging-houses, which require, and receive, frequent inspection. Dr. G. S. Glass, who has been acting as municipal health officer in the absence of Dr. Stuart Rose, on leave, at the conclusion of his report refers to the need for a new site for the municipal quarantine camp as soon as financial considerations render it practicable. Lectures on hygiene and public health to school teachers have been well attended and appreciated, and it is satisfactory to learn that the public press also shows a lively interest in these matters.

Public Health in Sierra Leone.

The colony and Protectorate of Sierra Leone is about the size of Ireland (30,000 square miles) and lies between the seventh and tenth parallels of north latitude, and 10° 40′ and 13° 21′ of west longitude. Freetown, the capital, is situated on the north-east corner of the peninsula on a fine natural harbour, formed by the mouth of the Rokelle or Sierra Leone river. The population of the colony (as distinguished from the Protectorate) was returned at the census of 1921 as 85,163 (47,654 males and 37,599 females). The birth-rate in 1921 was 18 and the death-rate 22 per 1000. The estimated population of the Protectorate is 1,456,148, composed of more than a dozen distinct tribes. An outbreak of small-pox of a mild type occurred in Freetown in April and May, 1921, otherwise the colony and Protectorate were comparatively free from epidemic disease during the year. The Colonial Hospital was completely destroyed by fire in 1920, but its reconstruction was nearing completion at the end of 1921; in the meantime temporary accommodation for a limited number of patients was arranged in the old Law Courts building. Fifty cases of small-pox and chicken-pox were treated at the Infectious Diseases Hospital with only one death. There were two patients at the Leper Asylum at the beginning of the year; there were no admissions and no deaths during the year. The number of European and American residents in the colony and Protectorate at the taking of the census was 1161 (officials 141, non-officials 701, and military 319) The lowest temperature recorded at the Town Hall Observatory in 1921 was 61° F. on July 8th; the highest 97° on Feb. 17th. There was an exceptionally heavy rainfall.

Public Health in Bangkok.

The receipt of a report on the health of Bangkok, Siam, comprising 170 pages and a number of supplemental statistical tables and diagrams, is welcome evidence of the progress of international sanitation, and of the extent to which British ideals of public health are being adopted in other countries. The first part of the report is concerned with the public organisation of Siam, and in a preliminary chapter the difficulties as well as the advantages of Siam are clearly stated. Among a population of over eight millions in the interior provinces there appear to be less than 200 certificated or similarly qualified physicians, a serious impediment to progress; but, on the other hand, Siam is able to organise its public health work in the full light of scientific knowledge, and thus has some advantages over those countries whose public health progress antedated the present advanced stage of medical science. As the prevention of plague, of hookworm disease, of malaria, of small-pox, and of cholera are among the chief problems of Siam, the value of the accurate specific knowledge which is available as the basis of preventive action is evident.

The report emphasises the need of a technical staff, having special training and adaptability; it also shows that at the head of affairs in Siam there are already skilled officers with a scientific insight into the needs of their country. The work in Siam is evidently impeded by imperfect vital statistics. Although actually complete figures are not available, local inquiries appear to show that 30 per cent. of infants die in the first year after birth, as compared with 8 per cent. in this country. Plague was first identified in Bangkok in 1904. Whether it was present earlier cannot be definitely stated in the absence of records; nor is there any exact statement of cases from that year onwards. One of the chief impediments to plague prevention is the use of bamboo for building. Round bamboo frequently harbours rats' nests, as well as many dead and living rats; and the recommendation is made that this form of construction should not be permitted without suitable provision for rat-proofing. Every province of Siam appears to have its quota of lepers, although there are no accurate figures. The disease is, therefore, rightly regarded as a serious national problem; adequate segregation, along with a campaign of education, is recommended as the only measure known to be successful in combating this disease.

We have not exhausted the interesting contents of this report; the Public Health Department is to be congratulated on its production, and it is to be hoped that monetary as well as skilled support will be given by the Government of Siam to the measures of administrative reform suggested in its pages.

Public Health in Barbados.

The census was taken on April 24th, 1921, and revealed an unexpected decrease in population, which was returned at 156,312 (10,429 whites, 111,677 blacks, and 34,206 mixed), or 15,671 less than in 1911, which in its turn was over 10,000 less than in 1891. The causes for the decline are given by the compiler of the census as emigration, declining birth-rate, and higher death-rate. Owing to the unreliability of the immigration and emigration statistics, however, the calculation of all three factors is affected. The birth-rate in 1921 was 32·62 and the death-rate 43·42 per 1000. The high percentage of females has been a constant factor in population figures in Barbados during the last 60 years; it has increased since 1861 from 53·6 to 59·7 per cent. The year 1921 was not a fortunate one in the matter of public health. The outbreak of typhoid fever which began in 1920 continued to increase and reached serious proportions, but has happily since abated. An outbreak of the disease in the prison was successfully controlled by the inoculation of all prisoners on entry. The public water-supply is carefully and regularly tested, so that the causes of the spread of the disease must be looked for in unsatisfactory sanitation and flies. A clinic for the treatment of venereal diseases was opened at the General Hospital. Excellent work was done and the number of patients attending increased steadily. Voluntary effort such as this can, however, only touch the fringe of the problem, which calls urgently for a united effort by the whole community. A series of experiments in the treatment of leprosy with ethyl esters of chaulmoogra oil has been in progress at the lazaretto the majority of those treated have shown marked improvement and the results seem very promising. Barbados enjoys natural advantages from a public health standpoint which few tropical places can equal and none surpass. Its climate is equable without extremes of heat or cold in any part; the soil is admirably drained by nature; there is an irreproachable water-supply, and no malarial fever. The present position in respect to sanitation, however, is not satisfactory.

ARTIFICIAL LEGS.

THE following is a summary of the general rules which, with the approval of the Minister of Pensions, have been issued for the guidance of medical superintendents of limb-fitting centres who are responsible for the ordering of artificial legs for pensioners. The rules were framed in accordance with the recommendations of the Committee of Inquiry on Artificial Limbs, of which Sir Archibald Williamson, M.P. (now Lord Forres), was chairman, and the membership of which included limbless representatives of disabled officers and men, doctors, and technical experts.

The artificial limb ordinarily supplied will be one of the Ministry's standard pattern legs (wood and leather), specifications for which have been drawn up and approved by the expert advisers of the Minister.

Where, however, it is obvious that a peg leg would be more suitable for the avocation of a pensioner, as, for instance, when he is a miner, fisherman, or an agricultural labourer, and the pensioner so desires, a peg leg may be ordered as one of his two artificial limbs.

Metal limbs may be supplied in the following circumstances: (*a*) New cases of amputation above the knee.

---

[1] Penang. Criterion Press. 1922.

especially those in which the amputation is higher than midway between the knee and the hip-joint, where a limb of this nature would, in the opinion of the surgeon, be preferable to one of the standard pattern limbs. (*b*) Other cases of above knee amputation where, owing to the weight or type of the artificial leg in the man's possession, he is handicapped in his activities or occupation, and where the change is therefore recommended by the surgeon. In such cases the second or spare wooden limb in the pensioner's possession is retained as his duplicate until it is worn out. (*c*) Cases in which a metal limb is not certified to be surgically necessary but where the pensioner shows a marked preference for a metal limb. In such cases a metal limb may be supplied when the limb already in issue is worn out, if the surgeon concurs. (*d*) The supply of metal limbs for below knee amputations is only admissible where special surgical or medical conditions exist, which in the opinion of the surgeon render the issue of a wooden limb unsuitable.

While every consideration is given to the desire a pensioner may express for a particular type of limb, the final decision must rest with the surgeon who is responsible for ordering a limb suitable to requirements of each individual case.

REGISTER OF MASSEURS AND MASSEUSES.

THE register of the Chartered Society of Massage and Medical Gymnastics for the period July, 1920, to September, 1922, contains the names of over 4000 masseuses and of nearly 300 masseurs. The preface contains a statement of the aims of the society, whose Royal Charter was granted on June 9th, 1920, together with a description of its constitution, a note of the rules under which members work, the conditions of their registration, and a page devoted to the Ling Association, which in July, 1922, gave up its own examination in massage and medical gymnastics and accepted the examinations of the society. A place-index and an obituary list complete the contents of the register.

CREMATION IN 1922.

SINCE the first English crematorium was established at Woking in 1885 over 27,000 cremations have taken place in Great Britain. From the annual report for 1922 of the Cremation Society we learn that 2009 cremations were carried out during the year, as against 1922 in 1921. Of these, 939 were at Golders Green, 193 at Woking, 189 at Manchester, and 186 at Norwood, the figures for the other 11 crematoriums being below 100 in each case. The Council of the Society report a satisfactory financial position and an increase in membership.

THE CHILD'S PROGRESS.

Messrs. Mellin's Food, Ltd., have recently issued a revised and enlarged edition of their "Progress Book," a register in which parents may keep a close and permanent record of a child's physical and mental development from birth to adolescence. In addition to the space reserved for height and weight records, details of vaccination and teething, and similar details, a section for the chronicling of medical history has been included which might well prove useful in later life. One page is set apart for finger-prints of parents and child, with instructions as to how they should be made. A sufficiently large collection of such data should have permanent value.

MORNINGSIDE HOSPITAL.

THE report for 1922 of the Royal Hospital at Morningside, Edinburgh, follows the tradition set by Sir Thomas Clouston in being a readable document, dealing not merely with the life and progress of the institution, but with current questions of interest to all those concerned with the insane. Prof. G. Robertson discusses the field of usefulness of psycho-analysis, the art of M. Coué, the function of the Church in healing (which is chiefly a protest against undue interference by the clergy), and lastly, the remarkable recent fall in the incidence of general paralysis. For this he suggests three possible reasons—the influenza pandemic, which may have effected prophylaxis just as malaria is said in Vienna to have effected cures, the fall in the consumption of alcohol, and lastly, the more efficient treatment of syphilis.

Morningside has entered on a new period in its history, now that parochial patients from Edinburgh have been accommodated elsewhere. The buildings thus vacated are being re-equipped, and will be used for the accommodation of private patients of limited means, and for the treatment of Service patients, who will henceforward occupy wards of their own. Plans have been drawn up for an out-patient department, and for the provision of all the means and appliances for clinical investigation which are available at a large general hospital. Morningside is evidently placed fortunately in being able to afford these improvements at the present time, and may well become a model from which the better asylums of the future will derive some of their inspiration.

THE OSTEOGRAPH.

THE osteograph is a simple and ingenious little invention by Captain S. L. Nathan, I.A.R.O., who has cut out all the bony framework, save the skull, in one small sheet of celluloid. The bones are separate, but can be used conjointly, as they are on the same scale, and thus in a few seconds the figure of a bone or of the skeleton can be produced in proper proportion by any student who may be quite incapable of drawing anything resembling the part. Students who cannot draw are much handicapped in their efforts to gain advantage from diagrams, &c., based on bony relations, and for them especially, but also for others, this device ought to be of considerable value. The small details of the bones are not given, but the general contour and salient points are all there, and appear to be quite accurately placed.

MUSIC AND MEDICINE.

THE soothing action of rhythmical sounds may explain the use by primitive races of incantations in the cure of disease, and of the wholesome effects of music in ameliorating certain morbid conditions of the mind there can be little doubt. We do not know in what great measure the perception of pain may depend on mental attitude, but whatever can quickly alter the mood must be regarded as a possible physical remedy. Poets and philosophers have thought alike, in the words of one of them, that "music may work strangely upon the mind and the body, the passions and the blood; to raise joy and grief; to give pleasure and pain; to give motions to the feet as well as to the heart; to compose disturbed thoughts, to assist and heighten devotion itself." For many years now music has been used in mental institutions for its possible effect in diverting the mind from morbid channels, and during the war a Vocal Therapy Society was successful in promoting the mental health of soldiers in hospitals and convalescent camps. For these reasons the appeal which has just been made by *Punch*, on behalf of the Royal Academy of Music, should have an interest for the medical profession. The Academy, the oldest of the musical schools in this country, has been compelled in its 101st year of existence to issue a public appeal for £19,000 in consequence of the lack of adequate foundation, and the failure of private subscriptions to meet the educational needs.

THE CHAULMOOGRA PLANT IN LEPROSY.

To the Editor of THE LANCET.

SIR,—In his letter which appeared in THE LANCET of Jan. 13th, Major-General Sir P. Hehir writes of an ancient story reported to be current in India about the cure of a leper king, Rama of Benares, by chaulmoogra, and affirms that chaulmoogra oil is derived from the kalaw tree. Although an Indian and an old man, with relations still living at Benares, I confess I am not aware of the story referred to, nor have I found mention of the kalaw tree anywhere in the course of my prolonged inquiry since 1915 into the origin, history, and uses of chaulmoogra oil. The story is presumably of Burmese origin, the kalaw tree being apparently the Burmese name for *Taraktogenos kurzii*, as shown by Mr. Rock of the United States.

In Appendix I., p. 24, of my pamphlet on "Indigenous Drugs of India" (published in 1918 by Messrs. Butterworth and Co., and reviewed in THE LANCET of Feb. 22nd, 1919), there is mention of chaulmoogra and of its synonyms in Indian languages, but not of kalaw, Burma and its language being quite distinct from India. In a pamphlet on chaulmoogra oil, published in 1917 (Nababibhakar Press, Calcutta) I identify the chaulmoogra plant as *Hydnocarpus wightiana.* This was known as *Tuvaraka* to the very early Sanskrit writers in India and is found growing in the forests of Malabar in South India. The seeds from the ripe fruit, as well as the oil expressed therefrom, were first exhibited at the Madras Exhibition in 1917. The confusion which arises in connexion with chaulmoogra is due first to the currency in the market of various oils under this name, and secondly, to the unfortunate practice amongst the medical profession and elsewhere to designate different plants as chaulmoogra. If it is once held that chaulmoogra, as an ancient Indian remedy for leprosy, is *Hydnocarpus wightiana* and nothing else, there will be no further confusion. In the Indian and Colonial Addendum to the B.P., 1898, oleum gynocardia was known as chaulmoogra oil, and was stated to be derived from the seeds of *G. odorata*, or of *Taraktogenos kurzii*. In the B.P., 1914, *G. odorata* is left out, and it is hoped that in the next issue of the B.P. a further change will be made, substituting *Hydnocarpus wightiana* for *T. kurzii*.

Finally, the efficacy of chaulmoogra in the treatment of leprosy lies apparently not in the use of its ethyl ester (Antilepral, p. 13 of the pamphlet l.c.) but in that of the whole oil, preferably in conjunction with pyrogallol oxide.

I am, Sir, yours faithfully,
J. C. GHOSH, B.Sc., F.C.S.

School of Chemical Technology, Calcutta.
Feb. 13th, 1923.

An Address

ON THE

TREATMENT OF DUODENAL ULCER.

Delivered before the Harveian Society of London on March 22nd, 1923,

BY SIR BERKELEY MOYNIHAN, BART.,
K.C.M.G., C.B., F.R.C.S. ENG.,
SENIOR SURGEON, LEEDS GENERAL INFIRMARY; PROFESSOR OF CLINICAL SURGERY, UNIVERSITY OF LEEDS.

IN a paper read before the Hunterian Society a few weeks ago I gave an account of the surgical treatment of gastric ulcer in my practice during the last 10 years. The cases of gastric ulcer and of duodenal ulcer operated upon during that period were summarised as follows. The total number of cases was 718. There were 531 cases of duodenal ulcer (men 433, women 98), and 164 case of gastric ulcer (men 83, women 81); in 152 cases one ulcer was present, in 12 cases two or more ulcers were present. There were 23 cases of gastric and duodenal ulcers together (men 10, women 13). In the total number of cases of gastric ulcer, 187, a duodenal ulcer was found, therefore, in 12·3 per cent.

During the 10 years there was no death from operation upon these cases of duodenal ulcer. The mortality in cases of gastric ulcer, alone or associated with duodenal ulcer, in which gastrectomy was performed was 1·6 per cent. I have operated upon 50 cases of jejunal ulcer; in 6 of these the primary operation had been performed by myself. The development of a jejunal ulcer is a most serious and disappointing complication of the operation of gastro-enterostomy.

RELATIVE MERITS OF MEDICAL AND SURGICAL TREATMENT.

When we are discussing the relative merits of the medical and the surgical treatment of duodenal ulcer, their immediate results have not alone to be considered. A patient who survives an operation for duodenal ulcer and leaves the hospital in good condition is often entered upon the records as "cured"; and a patient in whom, by means of medical treatment, a subsidence of symptoms has occurred has often, indeed perhaps always, the same cheerful and optimistic utterance expressed about his case. But surgical treatment, however successful its immediate result, is by no means the final event in the patient's history; and medical treatment is very often powerless to prevent a recurrence of the disease. In both cases the long view is necessary. And the long view reveals defects in both medical and surgical treatment of duodenal ulcer.

The medical treatment as usually carried out in this country is most effective if judged by its temporary results; it is disastrous if the long view is taken. The first defect which attaches to it is the uncertainty of diagnosis. It is, of course, well known that the diagnosis of duodenal ulcer, if the classical symptoms I described many years ago are present in their most complete form, is, as a rule, very accurate. The cases in which a diagnosis will then prove erroneous are few; but they do occur; and they may occur when least we expect them; and they occur when both the radiologist and the chemist are accomplices in our clinical error. The mimicry of the symptoms of duodenal ulcer is very close in cases of gastric ulcer; in cases of chronic appendicitis, especially where tuberculous glands are present in the ileo-colic angle; in cases of obstruction of the duodenum in its third part, by the superior mesenteric artery, by the ileo-colic artery, or by tuberculous glands, adherent to the duodenum, on either side of the superior mesenteric artery; in cases of chronic nicotine poisoning; or finally, in some cases of cholecystitis with or without stones. If the physician undertakes the treatment of a case of "duodenal ulcer," however confident he may be of his diagnosis, he may nevertheless be engaged with a case in which this lesion is not present; and the estimate he is then led to form of the value of medical treatment is quite fallacious. This does not often happen, but it occurs with a frequency which cannot be ignored.

NECESSITY FOR CARE AFTER RELIEF OF SYMPTOMS.

When medical treatment has resulted, as it will almost invariably, in relief of the symptoms, the most watchful and continued care of the patient is still necessary. Relief of symptoms, as I have shown in earlier papers, does not mean closure of the ulcer. Under such provocations as come from excessive work or anxiety, from chills, from over-smoking, from lack of restraint in matters of diet, a fresh attack may begin quite abruptly, and last for weeks or months. In the periods of quiescence the patient is not free from dangers; in them, as in the recurring attacks, the acute emergencies may develop with all their grave and urgent dangers. With the help of Prof. M. J. Stewart and Mr. P. J. Moir I have been able to obtain the following information as to the deaths from duodenal ulcer in the Leeds Infirmary in the last 10 years. In this period there have been 129 cases, in which death was directly attributable to hæmorrhage from duodenal ulcer or from perforation. There were 12 deaths from hæmorrhage; in all the ulcer was of the chronic variety. There were 117 deaths from perforation. In 12 of these there was an acute ulcer; in 4 of the 12 chronic ulcers also were present, and in each case it was the chronic ulcer which had perforated, the acute ulcer being merely incidental. In the remaining 105 cases the ulcer or ulcers were of the chronic type. Perforation, therefore, is found far more commonly in cases of chronic ulcer. A full clinical history is not always to be obtained, for even nowadays patients are brought in a moribund state to the hospital two, three, or four days after the catastrophe has occurred. But the records show that the very great majority of patients had undergone treatment for longer or shorter periods on a number of occasions.

MEDICAL TREATMENT OF GASTRIC AND DUODENAL ULCERS.

The form of medical treatment which has been sanctioned for many years in the case of gastric ulcers, however inappropriate it may be for them, is probably excellent in cases of duodenal ulcer. The fact that over 70 per cent. of the cases of duodenal ulcer, recognised at operation and therefore indubitable, show either a high normal curve or hyperchlorhydria when examined by the Rehfuss method; and the further fact that many of the cases of jejunal ulcer occur in patients who show the same evidence of high gastric acidity, are taken as evidence of the need for an "alkali" treatment. When the various "systems" of medical treatment were standardised it is extremely probable that the majority of the cases diagnosed as "gastric" ulcer were in truth suffering from other diseases; and that if an ulcer were present it lay, not in the stomach, but in the duodenum. The rarity of gastric ulcer, and the difficulty of its diagnosis, were not then recognised as they are now. The medical treatment of patients suffering from duodenal ulcer should be more successful than is the case with gastric ulcer. But in order to be so it must be carried out far more scrupulously, and for much longer periods than is now the custom. If physicians will realise that the methods of medical treatment at present adopted greatly exceed in danger, and in success fall far below those of surgical treatment, the methods at their disposal will no doubt be improved, and that sustained care of the patients which is most essential will be made the rule.

RESORT TO SURGICAL MEASURES.

When medical treatment has failed, not once only but perhaps many times, surgical measures will be deliberately sought. They may be hastily demanded in either of the acute catastrophes, hæmorrhage or perforation. For cases of perforation immediate operation is necessary. In some cases not only closure of the ulcer but the performance of gastro-enterostomy may be necessary. I was, I believe, the first surgeon to advocate this, in a paper published in THE LANCET in 1901.[1] It is true that many patients in whom closure of the ulcer alone is performed do well and have no further disability; but it is also true that those in whom it can properly be performed do better, that they run no greater immediate risk, and that they are not called upon to submit, as are so many of the other class, to a second operation for duodenal obstruction, or for a return of their dyspeptic symptoms. The matter is one that must be left to the judgment of the surgeon at the moment. My own view is that if the closure of the ulcer involves a narrowing of the lumen of the gut, immediate or consequential, and if the patient's condition is good, it is better forthwith to perform the short-circuiting operation. For hæmorrhage an immediate operation is rarely necessary. If possible a direct transfusion of blood is performed, and then, or at a later stage, an operation may be more safely undertaken. Though deaths do occur from hæmorrhage, sometimes before the surgeon can be summoned, they are rare in proportion to the total number of cases in which there is bleeding.

In connexion with the deliberate surgical treatment of chronic duodenal ulcers, three operations only have been practised with any degree of frequency, and all of them are still applicable in certain cases; they are: (1) Excision of the ulcer; (2) anastomosis of the stomach to the duodenum, with or without excision of the ulcer, or division of a cicatrix; (3) anastomosis between the stomach and the jejunum.

(1) *Excision of the Ulcer.*—This method, with repair of the wound in such manner as to avoid stenosis, has proved very satisfactory in the small number of cases in which I have been able to practise it. It is essential for the success of such an operation that the ulcer shall be small in size, single, and on the anterior surface; that it shall not be surrounded by a wide area of redness, mottling, or œdema; and that no extensive or dense adhesions shall have formed between the duodenum on the one side and the liver, abdominal wall, or gall-bladder on the other. Comparatively few cases fulfil all these conditions. Ulcers are often multiple, and one or more of them may be of large size. An ulcer which appears to lend itself most readily to excision is found on closer examination to be accompanied by a "contact" ulcer on the posterior surface. This ulcer, if small in size, may only be exposed to view when the anterior wall of the duodenum is incised for the purpose of removal of the ulcer which involves it. In such circumstances the "contact" ulcer may be cauterised, and its edges approximated by a few sutures. It is better, however, to abandon the intended operation of local excision and to perform Finney's operation of gastro-duodenostomy. If a large part of the anterior surface is involved in the ulcer, the wound cannot be closed until a plastic operation is performed. In all I have performed this operation of simple excision only 17 times. There has never been a recurrence of symptoms to a degree requiring further operative treatment; one patient, a fellow student, has had a few slight discomforts which are relieved by simple measures and by care for a few days in matters of diet.

(2) *Anastomosis of Stomach to Duodenum.*—The original operation of Heineke and Mikulicz proved a very unsatisfactory operation in our experience in Leeds. The very great majority of cases of "pyloric stenosis" are due to the healing, not of gastric, but of duodenal ulcers. When in the method of "pyloroplasty" the scar was divided in the horizontal axis of the gut, and the wound stitched up in a line at right angles to this, two consequences followed: either a contraction of the new scar occurred and obstruction again became evident, or the sutured incision became adherent to the abdominal wall or the liver, and the movements of the stomach were in consequence embarrassed. A very large proportion of the cases (every case upon which I operated myself) required a second operation, and for this reason the method of pyloroplasty was rightly discarded.

Finney's operation, "gastro-duodeno-pyloroplasty," was a great improvement upon the method of Heineke and Mikulicz. Finney, a surgeon of very large experience and of great wisdom, has never ceased to advocate the claims of this method, which in his hands and in the practice of other surgeons has given good results. In this operation the incision, passing through the pylorus, extends two to three inches down into the stomach a little above the greater curvature, and along the anterior surface of the duodenum to about the middle of its second part. The objections I find to it are that it cuts through a septic ulcerating surface, that acute ulceration is so often to be found round about the chronic ulcers, that the ulcers are often callous or œdematous, or intensely adherent to a neighbouring part, and that mobilisation of the duodenum is not always possible or easy. I have preferred in appropriate cases to make an anastomosis between the stomach and the mobilised duodenum at some distance from the ulcer. The ulcer is then treated first. It may be destroyed by the cautery and the seared edges of the wound brought together, or the ulcer may be buried by infolding the duodenal walls and covering the sutured line with a wisp of omentum, gastro-hepatic or gastro-colic as may seem best. At the same time any vessels running towards the ulcers are caught up by the deep interrupted sutures, and as they are tied the vessel is obliterated. A very free opening may be made between the stomach and the duodenum, an opening quite as large as that made in the operation of gastro-enterostomy. The conditions which I consider essential are that the ulcer or ulcers of the duodenum should be in a tranquil or healed condition; that there should be no œdema, no recent accession of activity in or about the ulcer, or any dense or wide-spread adhesions around it; that a free mobilisation of the duodenum shall be easily possible; and that there shall be no obstruction of the duodenum by the superior mesenteric artery, its right colic branch, or by adherent tuberculous glands. In this series of cases there are 28 operations of this kind. A sufficient mobilisation of the duodenum is by no means easily managed in all cases. In this respect conditions differ greatly. The extent to which the transverse colon and the mesocolon overlap the duodenum or become firmly attached to it seems capable of considerable variation. The number or large size of the vessels reaching the duodenum from its outer or posterior side may render the separation of the intestine very difficult. I have had to abandon this operation two or three times on finding that it was really not possible to get such freedom for the duodenum as I thought essential.

The results of this operation of gastro-duodenostomy have been excellent. It is without doubt the operation that one would always prefer if only the conditions essential to its success were more commonly present. There is no such thing as regurgitant vomiting, and I have never known a recurrence of ulceration in the duodenum, or the development of a fresh ulcer at, or near, the anastomosis. If such ulceration did occur there would still be the operation of gastro-enterostomy to which we could turn. If we had access to the cases at an earlier stage (assuming that surgical treatment then were necessary) this method would certainly be more often the chosen one. In reviewing the experience of the last few years I find that I practise the method with a gradually increasing frequency. It is more than probable that some of the cases treated a few years ago by gastro-enterostomy would be dealt with, if occurring to-day, by this method of gastro-duodenostomy, combined with excision of the ulcer, or its destruction by the cautery.

(3) *Anastomosis between the Stomach and Jejunum.*—There are few operations so completely satisfactory

---

[1] THE LANCET, 1901, ii., 1656.

as gastro-enterostomy, properly performed in suitable cases. What I have said with regard to error in diagnosis on the part of the physician applies here, but with greater force, to the surgeon. When the parts are before him for inspection it is the business of the surgeon who undertakes these operations to know whether an organic lesion is present or not. It is still, I regret to say, the practice of some surgeons to perform gastro-enterostomy in the absence of a structural lesion which alone can justify the operation. Such work is discreditable, and should be abandoned.

After-Results of Gastro-Enterostomy.

The after-results of gastro-enterostomy for duodenal ulcer are excellent. Over 90 per cent. of the cases traced consider themselves perfectly well. In the remainder the discomforts may almost be regarded as negligible, especially by comparison with the protracted suffering before the operation. There are two exceptions only to this statement: the first concerns the patients in whom a jejunal ulcer has developed. I have traced nine cases which had occurred after I had myself performed the original operation; the earliest case was operated upon in 1904. Of the nine cases I have had six under my own care. The incidence of jejunal ulcer in cases of duodenal ulcer treated by gastro-enterostomy may therefore be assessed at a little over 1 per cent., or let us say 2 per cent., to include other possible cases not traced, or cases with symptoms so slight as not to need further treatment. One only of the six cases I have operated upon myself has died after a second operation; the remainder have been "cured" by the removal of the stomach. But a second operation is a serious matter for the patients, and is never faced with quite the same courage or confidence as are displayed before the first operation. When we are gauging the risks which lie ahead in a case of duodenal ulcer about to be treated surgically, we must therefore include not only the mortality of the first operation, but the chance, however slender, that a second ulcer may form which in turn will need for its relief a second and probably a far more formidable operation. The total risk to life is, then, not more than 2 per cent., and the chance of complete relief is not less than 90 per cent.

Causation and Treatment of Jejunal Ulcer.

The causes of jejunal ulcer are not always clear. There may be one ulcer or many; the ulcer may be exactly on the suture line, or a little distance away from it, generally in the efferent, but sometimes in the afferent position of the bowel; an ulcer may be found in the stomach or in the jejunum two or three inches away from the anastomosis. The valvulæ conniventes have been described as withered or smoothed away in that part of the jejunum which is engaged in the anastomosis. I have never seen any change of this kind in any specimen. Many causes have been assigned for this most distressing condition. Among them are the following:—

(*a*) An unabsorbed suture of silk or thread dangling at the suture line from which it slowly suppurates its way out. Wilkie in particular has called attention to this. It is not, as is generally supposed, the stitch in the mucosa which gives trouble; this is always absorbed or discharged within a few weeks. It is the serous suture that lingers for months or for years. There is no need to use either silk thread or heavy chromicised catgut, of which I have found a complete loop still present at the suture line three years and nine months after the original operation. For many years now I have had no other suture material than the finest catgut, and there has been no single disadvantage from it.

(*b*) The development of a hæmatoma along the suture line at the time of operation; the blood-clot becomes infected, an abscess forms and bursts, and a cavity remains.

(*c*) Bruising of the parts by the clamps employed at the operation, especially by the jejunal clamp. The ulcer is rarely seen at the part of the intestine embraced by the clamps. The use of the clamps may be harmful if they are applied unskilfully, with too great pressure, or a pressure insufficient to arrest hæmorrhage. The operation is so simplified by the application of clamps that it is worth while taking pains to use them properly and to apply them carefully. To discard the clamps is to declare one's incapacity to make the best of them and is a criticism, not of the clamps, but of one's self.

(*d*) The recrudescence of an old infection in the mouth or in the abdomen (including the original ulcer) or elsewhere, or the outbreak of a new acute infection. Gordon-Taylor has recorded a case of acute appendicitis in which a jejunal ulcer rapidly developed a perforation. A search for all infections, both before and during the operation of gastro-enterostomy, is a part of the procedure that no one can now afford to omit.

(*e*) A persistent hyperacidity. Jejunal ulceration occurs in proportion far more commonly after operation for duodenal ulcer than for gastric ulcer. Over 70 per cent. of cases of duodenal ulcer have a high normal acid curve or hyperacidity. In our cases of jejunal ulcer examined by the Rehfuss method, a degree of hyperacidity, sometimes extreme, was present in most cases. It appears therefore in our experience, and in that of others, that a greatly increased acidity is usual though not invariable in cases in which jejunal ulcer is found. An even stricter after-care is consequently desirable in cases of gastro-enterostomy for duodenal ulcer in which continued hyperacidity has been noticed before operation.

I have operated upon six cases of jejunal ulcer in which no ulcer was found in the stomach or jejunum at the time the operation of gastro-enterostomy was performed. It is futile procedures of this kind that help to discredit the operation. To perform gastro-enterostomy in the absence of a lesion is as useless and impotent a procedure as trepanning for extroversion of the bladder. If that were practised criticism would fall not upon the operation performed, but upon the surgeon. It should be the same here.

The treatment of jejunal ulcer is very difficult. I have no knowledge of an undoubted case in which the symptoms have disappeared entirely and have long remained absent after medical treatment. The immediate results of medical treatment are good, but relapses are perhaps invariable. This is exceedingly disappointing, for the surgical treatment of this condition is apt to be difficult, and it is attended by a danger greater than that which attaches to the original operation.

Operations.

The following operations may be practised:—

1. *Excision of the Ulcer, with Local Repair of the Anastomosis.*—This has proved very unsatisfactory in my hands. In one case a third operation was necessary, and after it the symptoms recurred. Three operations, that is, had failed to relieve the patient. This was a case early in my experience, and it led me to abandon a procedure on whose results I could not count with confidence.

2. *Excision of the Ulcer with Closure of the Anastomosis.*—This operation is applicable in cases in which no ulcer was present in the stomach or duodenum to justify the original operation. If there had been no closure of the pylorus nothing more than this is necessary so far as the stomach is concerned. A search elsewhere in the abdomen may reveal the lesion responsible for the symptoms wrongly ascribed to duodenal ulceration.

3. *Excision of the Ulcer, Closure of the Anastomosis, and the Making of a New Anastomosis, Anterior or Posterior.*—If the jejunal ulcer is large, surrounded by œdematous tissue and adherent to the transverse colon, its existence may result in so large a gap in the stomach or jejunum engaged in the anastomosis that a repair of the old opening may be impossible. In such cases, if the original duodenal ulcer or its scar is present, the stomach and jejunum may be closed, and a new anastomosis made between an unchanged part of the stomach and a lower loop of jejunum. If the anterior method is adopted an anastomosis after the design of Roux may be preferred.

4. *Excision of the Ulcer, Closure of the Anastomosis, and the Performance of Gastro-duodenostomy.*—This is a very satisfactory procedure; it is relatively very easy and safe. It implies that such a condition of the parts near the pylorus and along the duodenum is found as will permit the mobilisation of the intestine and the making of a large anastomosis. By implication, therefore, the original operation should have been gastro-duodenostomy, not gastro-enterostomy.

5. *Gastrectomy.*—I have performed this operation more frequently as my experience of the condition enlarged. The operation is very difficult in some cases; it is, indeed, never easy. The jejunum is divided above and below the anastomosis. The distal part of the jejunum is closed and the side of this piece of the intestine is united to the cut end of the stomach after the gastric resection is complete. The proximal part of the jejunum, the part leading from the flexure, is united to the distal jejunum below its union with the stomach.

6. *Jejunostomy.*—There are cases in which a very serious hæmorrhage may have occurred, and in which pain is exceedingly severe. The patient's condition is grave, indeed perilous. To perform any extensive operation would almost certainly be to hasten the end. In such circumstances the operation of jejunostomy may be performed under a local anæsthetic, and through the tube liquid food may be given in large quantities. The "drip" method of Murphy may here be used with advantage. No food, liquid or solid, is given by the mouth for weeks or months, the stomach being at rest pain soon disappears. I have twice performed this operation. In one case gastrectomy had subsequently to be undertaken because of a further hæmorrhage; in the other the patient took no food by the mouth for five months, the tube remaining in the jejunum. As no distress followed, the tube was removed and the abdominal wound closed. This was done three years ago; no recurrence of symptoms has been observed up to the present time.

HÆMORRHAGE AFTER GASTRO-ENTEROSTOMY.

The second exception must be made in connexion with cases of hæmorrhage occurring after gastro-enterostomy. I have traced 11 such in my own series of cases. The hæmorrhage may be slight or may be very serious. Its cause is not always certain. In some it is an early, or the only, manifestation of the onset of a jejunal ulcer. Not all jejunal ulcers bleed, and there are other sources of hæmorrhage than such ulcers; but I always regard this symptom as possibly indicative of a new ulcer at the line of the anastomosis. The radiologist's examination is often most helpful; the crater of an ulcer may sometimes be demonstrated, or a degree of spasm provoked by the ulcer may seem to close or distort the opening between the stomach and the jejunum so that nothing, or very little, may pass through it. The hæmorrhage may come from the original duodenal ulcer, a fresh activity in which has developed probably in consequence of an acute infection elsewhere. Or it may come from the detachment of a suture of silk or thread from the anastomotic line. Or it may be due to causes at present indeterminate. In one case the patient suffered from splenic anæmia, and gastro-enterostomy had been performed elsewhere, under the erroneous impression that dyspepsia and hæmorrhage indicated the presence of a duodenal ulcer. In three cases upon which I have performed the second operation it has been an untreated duodenal ulcer from which the blood escaped; a large vessel entered the ulcer, which appeared as fresh and active as ever, the anastomosis notwithstanding. Hæmorrhage appears to be more likely to occur, after operation, in those patients who suffered from it before operation. In four patients the coagulation-time has been increased by over 50 per cent.; in two of these I operated the second time and could discover no source of the hæmorrhage. There was no ulceration, acute or chronic, in the duodenum, the stomach, at the suture line, or in the jejunum; the spleen was not enlarged, the liver not cirrhotic. These patients have been given an alien serum or collosol calcium or an intravenous injection of a 10 per cent. solution of calcium chloride at intervals. No further hæmorrhage has yet occurred in any of them, but I am not sanguine as to the success of any of these modes of treatment since intervals of a few months or years between attacks of hæmorrhage are not unusual.

Balfour has recorded a case of recurrent hæmorrhage after gastro-enterostomy in which, finally, he removed the spleen. Not a few cases are recorded of hæmorrhage occurring from the original ulcer after gastro-enterostomy has been "successfully" performed. One such case occurred in my own practice. It was this case which helped to convince me that local treatment of the ulcer, in addition to the short-circuiting operation, was always desirable. The occurrence of hæmorrhage after gastro-enterostomy has now been noted so frequently as to make it, in my opinion, a matter of absolute necessity to obliterate the ulcer as completely as possible. Mitchell, of Belfast, showed, some years ago, that a well-infolded ulcer speedily disappeared. It is therefore enough, as a rule, to bury the ulcer by infolding the wall of the duodenum around it. This in effect closes the pylorus, but it is not in order to close the pylorus that the sutures are introduced. Closure, indeed, without division of the gut is impossible; after the lapse of a few months, or less, food will again begin to trickle through the duodenum; this is in no degree harmful, and no doubt the physiologists would say that it is to be desired. Many years ago a patient upon whom I had performed gastro-enterostomy for duodenal ulcer made a very good recovery and was for a time completely relieved of all his dyspepsia. About three years later the symptoms returned as severely as ever, and the duodenal ulcer perforated. An operation performed in haste in the country was fatal. There is a further reason for direct treatment of the ulcer. Such an ulcer is a septic place; the crater is full of infected material, capable of inoculating other parts. The "contact" ulcers not infrequently seen, both in the duodenum or in the stomach, are one evidence of this; the acute ulceration round about a chronic ulcer is another; it is recognised by the mottling of the gut around the ulcer when the area is lightly stroked with gauze. After gastro-enterostomy is performed the infection in the ulcer has access to the stomach, and the new suture line may soon be implanted with organisms which hasten to grow there. We should therefore expect jejunal ulcer to occur more frequently among the cases in which the duodenal ulcer remains untreated. It certainly appears to be true that the incidence of jejunal ulcer is lowest in the practice of those who secure the destruction of the duodenal lesion. In my opinion the direct treatment of the ulcer should never be omitted.

RESULTS OF GASTRO-ENTEROSTOMY.

The operation of gastro-enterostomy has been greatly discredited in consequence of its performance in grossly unsuitable conditions. Its very success has been against it. The results, when the operation is undertaken for an appropriate reason, and in a suitable case, are, I think, unequalled by those of any other of like magnitude in surgery. It is the extension of the method to the case for which it is not befitting that has brought the discredit which in such cases it thoroughly deserves. It would be a fairer decision to blame the surgeon rather than to quarrel with the operation. The operation has been so developed technically that it now seems easy to perform. But it is not in truth so easy as it seems if flawless perfection is to be attained. The operation is sometimes very clumsily done. The opening is made too small, it is placed in the wrong position far away from the greater curvature, it involves a part of the jejunum near its mesentery, instead of the anti-mesenteric line. The anastomosis at its lower end is sometimes brought close to the transverse colon, to which it soon becomes adherent. A loop may be left between the flexure and the anastomosis and this part of the gut may be twisted on its long axis. The suture line may be bruised because the clamps do not adequately control the blood supply. These are only some of the technical faults. As much as most operations in surgery, this one requires care, neatness, and accuracy if a perfect result is to come from it.

The operation upon a case of duodenal ulcer is in itself only an incident, though the most salient one, in that long series of events which together make up the treatment of the patient. There must be adequate and scrupulous preparation and investigation before operation, the most faithful observance of the full ritual during the operation, and a continual watchful care after operation, if full success, not only immediate but distant, is to be attained.

AFTER-TREATMENT FOLLOWING GASTRIC OPERATION.

The after-treatment of patients upon whom any gastric operation has been performed is therefore extremely important. It is necessary to give the most careful and most explicit instructions, for not a few patients may be experiencing a freedom from pain, and an enjoyment of food, that may have been denied to them for many years. Unless a warning is given, and even if it is, the bounds of prudence may soon be overstepped. Among the most harmful of habits for all these patients is smoking. We have found that in many cases of jejunal ulcer a hyperchlorhydria is present, and may be extreme. If a Rehfuss meal is given to a patient accustomed to tobacco at a time when he is not smoking his normal "curve" may be recorded; if a second meal is given while a pipe is being smoked the increase of gastric acidity is very striking. An "attack" of duodenal ulcer often follows an orgy of tobacco; and many attacks are checked by abstinence from it. "Attacks" ascribed to duodenal ulcer are sometimes due only to nicotine poisoning, and I have not seldom rescued patients from impending operations by noticing their deeply-stained fingers and by prescribing for them a respite from tobacco for a few months and a diminished indulgence in it for ever. The close mimicry of "hunger-pain" in nicotine intoxication appears to have escaped notice.

At Leeds Infirmary the following instructions are given on a printed form to all patients after operation:—

1. Masticate the food thoroughly. Never hurry over meals.
2. Do not smoke for three months after the operation and always in strict moderation. The greatest danger lies in excessive smoking.
3. Avoid vinegar, lemon, condiments and sauces, salads, raw vegetables (celery, lettuce, &c.), pickles, pastry, sour fruit, currants, raisins, figs, lemon-peel, nuts, new bread, tough meat.
4. Take in small quantities only green vegetables (preferably passed through a sieve); meat cooked a second time.
5. Take small, light meals of simple foods for the first few months and have a very light meal (e.g., boiled milk, Benger's food, or arrowroot with a biscuit) at or near 11 A.M.
6. Alcohol, if taken at all, only in moderation; no clarets.
7. Butter and cream may be taken freely.
8. The teeth and gums and the inside of the cheeks should be brushed with care two or three times daily, and visits to the dentist should be made regularly.

DETAILS OF ROUTINE.

In our operative work we have developed a routine. The dentist, the radiologist, and the chemist all make their attack upon the patient first, unless, as sometimes happens, there are reasons contrary to this custom. While the patient is submitting to these ordeals his capacity to stand an operation is gauged, and if it prove weak we endeavour by all means in our power to fortify it. Glucose is given by the mouth, and by the rectum continuously in 15 per cent. solution, with carbonate of soda, never with salt. A direct transfusion of blood may be given once or oftener. In cases with great obstruction where the tissues are parched and desiccated, and a fear of acidosis after operation may be entertained, an intravenous infusion with carbonate of soda, with or without glucose, is found helpful. If a patient is profoundly ill these measures may be followed by a rest in one of our convalescent hospitals in the country for two or three weeks. An operation upon any patient is among the most sacred things of life. If a man trusts you with his life you must be worthy, and it is impossible to take the matter too seriously. There is no hurry to get the operation over; yet there is never a needless delay. I am most faithfully and loyally served by the sisters in my wards and my home; and I often tell the visitors who honour me by watching our work that these helpers of mine will not allow me to kill a patient, however hard I may try! A surgeon, more than most men, owes the success of his work to those who help him.

The technical details of gastric surgery are now known to all. We operate as quickly as may be necessary, doing less or more according to the patient's needs, and to his power to bear all that we think right to do. There is neither haste nor panic; if a difficulty comes we meet it quite cheerfully and perhaps with a little pride that something more is asked of us. A general inspection beginning at the cardiac orifice of the stomach is first made to confirm, or refute, the original diagnosis; if we are found to be wrong the error must be fully and frankly admitted, and we must set out to profit by a fresh discovery. We quote Saul, who went in search of his father's asses and found a kingdom. We recognise that, except in cases where peril is grave and imminent, an operation upon the stomach or the duodenum implies an examination of the gall-bladder, the removal of the appendix if it has not previously been removed (and sometimes even if it has!), a general scrutiny of the mesentery for tuberculous glands, of the colon, pelvis, kidneys, and the spleen; in some of them a latent causal infection may be laid bare. One of the great hopes I have cherished with regard to surgery is that it may be used not only to relieve the dangers and distress that at the moment menace the individual, but also to enlighten us with regard to the earlier stages of disease in the organs we can examine during life. When I coined the phrase "The pathology of the living" I did so in order to show that surgery might be used not exclusively as a therapeutic resource, but also as a means of inquiry. And the results of this inquiry have already been stupendous and revolutionary.

This wide and detailed examination which attempts the exact correlation of the symptoms with the pathological conditions discovered, constitutes a form of research than which few can be so difficult or bewildering. In laboratory research the simple question that is put may be answered in one way or another; each answer leads to other plain questions, and so the growing inquiry goes on; the factors interfering with question and direct reply being few. In the research carried out upon the human being during the course of any disease, especially if it be treated by an operation which permits an extended survey of the parts, a whole series of concomitant conditions demand inquiry and balanced consideration; all may affect the course of the disease, explain its cause, or lead to a discovery of its unsuspected relations with other diseases. Clinical research is of all inquiries the most difficult in medicine, making heaviest demands upon the knowledge, the powers of observation, the imagination, and the intellectual integrity of those who engage in it; laboratory research by comparison is bumblepuppy. The Royal Society seems to cling to a contrary opinion, to the great detriment of the regard in which its Fellowship is held.

NECESSITY OF UNDERSTANDING BETWEEN PHYSICIAN AND SURGEON.

The problem of the treatment of duodenal ulcer is one which concerns both the physician and the surgeon. The separation between them, unhappily very wide and perhaps unfriendly, is to the grave disadvantage of medicine. In the treatment of these and of other conditions, a good understanding between them is essential to the welfare of the patient. If the physician judges of surgery after contemplation only of its failures, he should be persuaded to remember that the successes of surgery are won from the failures of medicine; and that the failures of surgery, serious as they are admitted to be, are a very trivial proportion in the total volume of rescue work. If the surgeon is prone to criticise the ineffective control of these diseases exercised by the physician, he may remember that diseases affect patients, and that patients do not readily submit to discipline when a complete subsidence of their symptoms has been quickly produced by a treatment which the physician desires to continue for weeks or months beyond this stage.

I should like to say, with every respect, that those who practise medicine have not availed themselves fully of their opportunities of learning in the operation theatre. In the year 1913 the chief assistant of one of the most famous physicians in the world, a voluminous writer on gastric diseases, spent some weeks with me. On the first day of his visit he saw an operation for duodenal ulcer. I demonstrated the pyloric vein, the ulcer, the condition of the stomach, and the usual points disclosed in such an operation. He could hardly contain his excitement; the experience being evidently a very novel one. So I asked, "Has Prof. X (his chief) ever seen a duodenal ulcer in a living patient?" and he replied, "Oh! well, I *think* he has." I wish the visits of physicians to surgeons (and the return visits also, they are no less necessary) were more frequent. Physicians would thus realise how difficult a problem that of treating gastric and duodenal ulcers really is, and they would perceive, too, how senseless it is to talk of medical treatment for such conditions as cholelithiasis. The whole treatment of these and of other diseases is not confined to the temporary relief of symptoms, but implies also both a discovery of the near or distant cause or causes, and a removal of the structural changes which result, whenever these are possible. I think it is a reproach to medicine that the surgeon should be compelled to operate so frequently for gastric and duodenal diseases. Such ulcers ought surely to be cured, far more often than they are, by medical treatment. Physicians who acquaint themselves with the pathology of a living gastric or duodenal ulcer realise how protracted and how scrupulous the medical treatment of so grave a lesion must necessarily be. If the practice of a few physicians became the custom for all, then perhaps we might find a way of escape from the grave disadvantages which result from the so frequent divorce of mind from hand in medicine.

A Lecture

ON THE TREATMENT OF EPITHELIAL TUMOURS OF THE URINARY BLADDER,

BASED ON A CONSIDERATION OF 162 CASES PERSONALLY OBSERVED AND TREATED.

Delivered at the Mayo Clinic, Rochester, Minnesota, U.S.A.,

By FRANK KIDD, M.A., M.Ch. Camb., F.R.C.S. Eng.,

LATE SURGEON TO THE LONDON HOSPITAL, ENGLAND; MEMBER OF THE INTERNATIONAL SOCIETY OF UROLOGY; MEMBRE DE L'ASSOCIATION FRANÇAISE D'UROLOGIE.

(Concluded from p. 586.)

Group 6.—Total Cystectomy.

I can only bring forward five cases of total cystectomy, as the operation of partial or subtotal cystectomy has diminished the need for considering total cystectomy. Many of my cases of partial cystectomy had more than three-quarters and some as much as seven-eighths of the bladder removed, so that they were very nearly total cystectomies. If a case of papilliferous or ulcerating carcinoma is seen in the first few weeks of its bleeding I have been able in several cases to effect a cure by means of diathermy applied through the cystoscope. If a case is seen fairly early when the malignant ulcer or polyp is confined to one side of the bladder and involves but one ureter, then partial cystectomy can bring relief and often cure. Total cystectomy seems therefore to be indicated under two conditions: (1) when an early papilliferous or ulcerating carcinoma of the bladder is seen growing from the base or trigone of the bladder and involving the mouths of both ureters, and (2) when the patient is suffering from multiple malignant polypi which recur in large numbers again and again and tend to fill the bladder.

My cases of cystectomy all come under the first heading. None of the cases I met with coming under the second heading were willing to submit to total cystectomy. The majority of the cases that applied for treatment suffering from sessile carcinoma of the base of the bladder were too far advanced to permit of cystectomy. The growth had already spread deeply into the pelvic cellular tissues, or into the side walls of the pelvis, or into the peritoneum or rectum. Such cases are obviously unsuitable and need drainage combined with open diathermy or radium or to be left alone. It is therefore only a few cases that can be selected for cystectomy.

What seems to prevent the operation from being successful in any but the most exceptional case is *the poor functional state of the kidneys* rather than the technical difficulties of the operation. A case will only be selected for cystectomy where the growth surrounds both ureters. By the time this has happened both ureters are widely dilated from back pressure and the kidneys correspondingly depressed in function. It is not feasible, as in prostatic cases with depressed kidneys, to drain the bladder first and do a two-stage operation after the kidneys have recovered, as the block is higher up—namely, in each ureter. Merely to cut across the ureters and divert them on to the skin or into the rectum does, it is true, provide free exit for the urine, and might seem to offer a hopeful first step for a two-stage operation. But as will be seen from a consideration of the cases of ureterostomy, that operation is nearly as dangerous as a one-stage cystectomy, the fact being that once the ureters are blocked and dilated this renders them hypersensitive to ascending infections in the lymphatics of their walls with consequent pyelitis, anuria, and death. The dilated ureters on each side will, therefore, continue to render total cystectomy seldom successful, though it is, I believe, justifiable in a few exceptional cases to attempt it, as a few successful cases have been reported. It should only be recommended after the full risks and dangers have been pointed out and when the friends know that it is the one small hope of a successful issue from a terribly painful disease which is bound to be fatal. A perusal of the literature suggests that others have experienced the same misfortunes.

None of these cases of cystectomy lived for more than three weeks. Two died of primary shock within less than three days. Two died from ascending pyelitis and anuria within a week. One lived for three weeks and, as far as his ureters and bladder were concerned, was doing well, but he developed intractable diarrhœa and died of exhaustion. The post-mortem examination showed that he had tuberculous ulceration of the small intestines. His kidneys were acting satisfactorily and his bladder wound had healed. In three of these cases I brought out the cut ureters on to the skin at the side of the loin. This step does not take a few minutes if small stab wounds are made and the cut ureters pulled out on to the skin through them, catheters being stitched into their openings. It certainly diminishes the risk of shock, but if successful it has the disadvantage that a urinal must be worn. In two cases I stitched the ureters into the rectum by Coffey's method. This step adds to the length of the operation and increases the risk of sepsis. One of these cases was a young woman of 34 with a malignant ulcer covering the whole trigone and surrounding both ureters. In four cases post-mortem examination showed that all traces of carcinoma had been successfully removed. In the fifth case I made a mistake in selection. The growth had spread extensively into the peritoneum, a point I had missed, but having cut across the urethra and prostate by a preliminary perineal incision I had to proceed and I did get the bladder out, but clearly I had not removed all the growth.

I think that we shall be bound in the future to pay attention to the results of renal function tests in these cases. Even if the growth seems an early and favourable one, if the renal function tests are deficient we shall have to remain content with diverting the ureters in the hopes of renal recovery and the outside possibility of cystectomy at a later stage. The only case of successful ureterostomy I have had refused resolutely to proceed to cystectomy later, as ureterostomy had so satisfactorily eased his sufferings. In cases of multiple malignant papillomata I feel that there may be a field for developing total cystectomy, but in the future, bearing in mind the work of Delfino, I would propose to cut away the bladder and stitch the stumps of the ureters to the urethra in the hope that a new bladder would grow therefrom. Having removed more than half the trigone and seen the bladder regrow, I am prepared to find that Nicolich did not express the whole secret when he assumed that the trigone must be left behind to act as a source of new muscle fibre. It is possible that the ureters and urethra can supply the necessary young muscle fibre cells. I am in hopes that the work of Delfino may make a fresh step in the progress of bladder surgery. He has shown (1922) that if in the dog the whole bladder, including the trigone, is removed, and if the ureters are merely stitched to the back of the urethral stump and the lower part of the abdominal wound left open and drained, that a new bladder wall containing muscular fibres will grow in the space left. Nicolich is said to have corroborated these results in two clinical cases. Schwartz has also published work that bears on this subject. My hope then is that we may cease to have to consider implanting the cut ureters on to the skin or into different parts of the bowel, and may be able to persuade a new bladder to grow out of the ruins left after a total cystectomy. If this proves possible it may prove an advance in bladder surgery.

GROUP 7.—URETEROSTOMY.

Of six cases of diversion of the ureters on to the skin or into the bowel, five died within three weeks from ascending pyelitis. Four were cases of diversion into the upper part of the rectum or pelvic colon, and two of diversion on to the skin of the side of the loin. The ureters were dilated in every case and hence hypersensitive to infection. All these cases were relieved of their terrible strangury as regards the bladder, so that their ends were peaceful (anuria and coma). The successful case was a man aged 56, with the most frightful agony from his irritable bladder. I diverted both ureters into the rectum successfully. Four months later he wrote to say that he was perfectly comfortable and that the only thing that troubled him at all was his wife's temper. He had to go to stool every four hours and empty his rectum of water. In between he could hold it completely. He died five months later of coma. Curiously enough I had better success from diversion into the bowel than from diversion on to the skin. A successful diversion into the bowel leaves the patient in every way more comfortable than a successful diversion on to the skin when he has to wear an apparatus which needs a good deal of attention. However, he is in no way worse off than a man after permanent cystotomy —many of these patients lead comparatively comfortable lives for a time—and little worse off than after a colostomy.

GROUP 8.—PERMANENT DRAINAGE.

This group contained 18 cases of permanent cystostomy. Only 18 patients seemed to need or would consent to permanent drainage of the bladder above the pubes followed by the wearing of a silver shield and urinal. This operation in inoperable cases that are complaining of agonising strangury or constant clot retention may be a great boon. It brings immediate relief of suffering and often appears to prolong life for six months up to a year or more. One case is worthy of note, occurring in a boy aged 3 years. He was brought into hospital suffering from complete retention of urine. I opened his bladder and found it full of large jelly-like growth which I thought must be myxomatous sarcoma. Microscopic investigation showed that the growth was true epithelial carcinoma undergoing cystic degeneration. I can find no mention in the literature of a similar case. The question suggests itself—why not divert both ureters rather than drain the bladder? The answer is that the mortality of ureterostomy stands very high, that of cystostomy low. Again, by opening the bladder it is possible to apply open diathermy or radium treatment.

GROUP 9.—TREATMENT NOT ADVISED OR REFUSED.

In 24 cases nothing was done. In addition to these 24, treatment appeared inadvisable or was refused in a considerable number of cases of inoperable carcinoma of the bladder, met with as out-patients; these were not admitted to hospital and so do not come into the records. A few of the 24 refused treatment, but most of them, though inoperable, were in comparative comfort, so that there appeared no adequate reason for surgical interference. They were left alone and subsequently died of anuria and uræmic coma. It is well to remember that cancer of the bladder may, in some cases, run its course and end in death without causing any unbearable suffering—i.e., suffering that is not readily controlled by fortitude and opiate drugs. Three of these cases were of carcinoma of the sigmoid invading the bladder from without. One case had attended a physician for three years complaining of hæmaturia. At each visit the physician had said "If my medicine does not stop your bleeding you will have to be cystoscoped." The medicine proved effective for three years. Cystoscopy then revealed an inoperable carcinoma of the bladder. In the not distant future physicians will be expected to publish the mortality of drug treatment, just as surgeons at present are expected to publish the mortality of operative interference. The drug mortality of some physicians is a very high one, yet few physicians have ever realised that they also possess a treatment mortality, which can be compared to the operative treatment mortality of the surgeons.

GROUP 10.—RADIUM TREATMENT.

Two cases were submitted to the highest dose of radium it was possible to collect, left in situ for 36 hours after a preliminary cystotomy to relieve retention. Both patients died within four months. The only effect of the radium appeared to be that it stopped the hæmorrhage permanently. Three patients, all women, were treated solely by radium, applied for many hours daily per urethram and every day for a week at a time. In the first two there was a fairly early malignant ulcer between the ureters which prevented partial cystectomy. In the third there were multiple recurrent papillomata filling the bladder after previous operations by other surgeons. I advised a trial of radium rather than total cystectomy. In a woman treated in 1913 after two courses of radium I could see a year later with the cystoscope that the malignant ulcer had skinned over on the surface, bleeding had ceased, and cystitis was cured, but underneath the healed ulcer I could see that traces of deep growth still remained, though there was very little, if any, thickening to be felt per vaginam. I have completely failed to trace this patient later than 1914. One woman died a year later despite the radium treatment. One woman, treated in May, 1921, is still alive in August, 1922. Her pains are lessened but she still has hæmaturia; she is not cured.

Radium appears to act as an intense selective destroyer of cancer cells that lie in its immediate neighbourhood. If it fails to kill the cells that lie deeper it may even stimulate them into more active growth. It may cause a malignant ulcer of the bladder to skin over for a time and so may cure a cystitis and stop hæmorrhage, and in this respect the results of radium treatment are apt to be deceptive. In some cases radium is said to render an inoperable case operable. Nevertheless, I feel that we are still a long way from the time when radiant energy as applied by means of radium or the Rontgen rays will hold out a better hope of permanent cure than a well-designed operation. Certainly I am as yet aware of no results from radium treatment which can compare with a successful cysto-diathermy treatment or a successful subtotal cystectomy. I should reserve radium, as yet, for early malignant ulcers lying between the ureters, especially in women, and for cases of multiple recurrent papillomata which fill the bladder. I should be prepared to advise partial or total cystectomy once there was evidence in any particular case that radium was doing no good, or, even if it appeared that radium had checked the superficial growth and so rendered operation less difficult and more likely to succeed. It is also justifiable to use radium, Rontgen rays, and open diathermy for surgically inoperable cases, giving a guarded prognosis.

I believe that radiant energy can fulfil a useful rôle in pre-operative and post-operative treatment, and also that in the future when it can be not only measured accurately but focused minutely then it may yet prove a curative agent. B. S. Barringer (1920, 1921) states that in his opinion, if surgery can cure 15 cases in 100, radium can cure 20. Barringer appears to have seen some definite cures from radium (1917). I feel that he underestimates the powers of successful surgery. I am able to report out of 80 cases submitted to surgical and diathermic attacks 41 known cases of cure, some up to 11 years since their treatment, and this underestimates the position; also out of 28 cases submitted to partial cystectomy 11 known cases of cure. This is better than Barringer's 15 out of 100. In Barringer's latest paper, out of 41 cases treated by radium during 1916–17 only seven can be stated to be free from carcinoma, only one more than three years since the treatment. I fail to see that Barringer has yet made good his position. Though it must be agreed that radium can cure a few cases of bladder cancer, it is difficult to prognosticate which ones, so that I feel we are giving our patients the best advice if we advise cysto-diathermy or subtotal cystectomy rather than radium treatment in the present stage of progress, and reserve radium for cases that are not suitable for these measures. Radium may arrest a growth and yet give rise to so severe a burn that the patient is left with an intractable cystitis, which may be more painful than the disease for which the radium was employed. It is well to bear this in mind. I understand that the results of radium treatment in the hands of Barringer and Bumpus are steadily improving. Instead of trying to produce a gross reaction on cancer and tissue cells from a large dose of the element itself they are now endeavouring to produce a lethal action on the cancer cells alone by scattering glass emanation tubes at regular intervals throughout the growths and leaving them there. In this way they claim that they are getting a wider lethal action on the cancer cells without producing necrosis and burning in the normal tissues. We must not close our eyes to this work, and I hope to see it develop. Nevertheless in the types of case suitable for radium treatment I am not sure that open diathermy may not eventually prove to give better results.

GROUP 11.—WRONG DIAGNOSES.

In these 162 cases I can only plead guilty to having made a wrong or doubtful diagnosis of tumour of the bladder in two cases, to such accuracy has the cystoscope brought the diagnosis. Our mistakes teach us more than our successes and should be recorded.

CASE 1.—Male, aged 40 in 1914. Two years strangury and hæmaturia. Cystoscopy without anæsthetic. "Bald smooth tumour projecting from the neck of the bladder on the left side. Is this a myxoma or a malignant bald papilloma or is it a senile enlargement of a prostatic lobe?" I was puzzled and advised exploration. Eventually the "tumour" turned out to be a prolapsed ureter containing a stone, which was successfully removed.

CASE 2.—Male, aged 62 in 1918. Three months' difficulty and slow stream. Cystoscopy without anæsthetic. One pint of residual urine. "There appears to be a large sessile carcinoma on the base of the bladder between the ureters." Exploration advised but nothing done. His doctor writes four years later to say that the patient is quite well. This must have been a case of extensive inflammatory cystic œdema of the trigone of the bladder due to cystitis behind an enlarged prostate, or else it was a case of spontaneous cure of cancer. I have observed spontaneous cure of proved carcinoma of the stomach.

Bladder lesions which may be mistaken for tumour unless care is exercised are acute inflammatory œdema of the mouth of a tuberculous ureter, a similar ureter due to colon bacillus inflammation, a stone impacted in the lower end of the ureter, and inflammatory papillomata described above. I venture to think there are few lines of surgery in which it is possible to attain such accuracy of diagnosis in dealing with tumours of a deep viscus.

GROUP 12.—TRUE EPITHELIAL PAPILLOMA OF THE MALE URETHRA.

I have included one case of true epithelial papilloma of the male urethra, as it is a condition very rarely encountered.

Male, aged 40, sent to me from a distant part of the world, where he had been treated for two years as a case of gonorrhœa; this in spite of the fact that he persistently pointed out that he suffered from a urethral discharge of blood and not of pus and that he went with his wife regularly during the time without any evil consequences, a fact which escaped the notice of his doctors. The aero-urethroscope showed me the presence of six long-pedicled papillomata hanging from the roof of the penile urethra 3 to 4 inches from the meatus. These resembled papillomata of the bladder and were quite unlike the ordinary gonorrhœal wart. I slit the penile urethra right down along its floor and destroyed each papilloma completely with a large diathermy needle, having first removed one for section. I stitched up the urethra, which healed by first intention. The patient writes two years later to say that he is perfectly well. The sections made of these growths showed that they almost exactly resembled simple papillomata of the bladder. Had their origin not been known the pathologist would have named them as simple papillomata of the bladder.

CONCLUSIONS.

1. In cases of papilloma of the bladder of a benign type diathermy as applied through the cystoscope holds out at least a 90 per cent. chance of cure without the risk of opening the bladder. To open the bladder and snip out such tumours should therefore be considered as an unnecessary interference that possesses a definite risk to life.

2. In cases of papilloma of the bladder of doubtful malignancy, it is possible to obtain a certain number of cures by means of diathermy applied through the cystoscope. Nevertheless, if diathermy fails to show an adequate destructive reaction in the tumour after at most three treatments, it should be given up and sub-total cystectomy shall be carried out instead.

3. In cases of malignant papilloma, early papilliferous carcinoma, and even of very early ulcerating carcinoma of the bladder, sub-total or partial cystectomy marks a great advance in bladder surgery. It should render the old intravesical operation obsolete except in a few isolated cases. It is an operation of considerable technical difficulty and presents a definite risk to life, but when successful it leads to a higher percentage of real cures than after the older type of operation, as its principles are based on a firmer pathological foundation. All cases of partial cystectomy should be followed up at regular intervals by means of cystoscopy.

4. Total cystectomy has been rendered almost obsolete by partial cystectomy, diathermy, and radium. It should be reserved for cases of multiple malignant papillomata that defy other treatment, and for a few favourable cases of early carcinoma involving both ureteric openings.

5. Ureterostomy presents almost as great risk to life as total cystectomy. When successful it brings great relief, and it may be used as a preliminary to total cystectomy in a few favourable cases.

6. Radium has in my opinion not yet justified its claim to supersede surgery. The future may decide otherwise when we learn to control radiant energy. Nevertheless, it has already established a claim to our very closest consideration. In the present state of knowledge I believe that it has already replaced total cystectomy. That is to say, for that class of case in which we should formerly have considered cystectomy, we should now prefer to advise radium treatment, combined perhaps with open fulguration and deep Rontgen-ray therapy. Again, we should cease to remain content with simply draining or leaving alone so-called inoperable cases. We shall advise them to have their bladders opened and one of two courses pursued—either open diathermy, or fulguration combined with the implantation of radium-emanation glass tubes, perhaps followed up by deep Rontgen-ray therapy and cystoscopic application of radium and diathermy.

Throughout this paper I have endeavoured to speak of four types of epithelial tumours of the bladder: simple papilloma, malignant papilloma, papilliferous carcinoma, ulcerating carcinoma. Perhaps a better classification would be pedunculated tumours, simple and malignant and sessile tumours, papilliferous and ulcerous. Clinically we can recognise these four types of epithelial tumours of the bladder.

I wish to record my thanks to Dr. Franklin H. Martin and the librarians of the American College of Surgeons for their help in gathering together for me a large body of the literature dealing with my subject. Their willingness to assist surgeons of all countries in preparing a list of the literature of any subject is, I believe, a forward step of immense significance for the future.

THE THERAPEUTIC ACTION OF BISMUTH IN SYPHILIS.

BY C. LEVADITI.

(From the Institut Pasteur, Paris.)

IN a recent contribution to the *Presse Médicale*[1] I discussed the question of the use of bismuth, particularly of basic tartro-bismuthate of potassium and sodium (trépol) in the treatment of syphilis. Since the publication of that article, numerous reports have been added to the collection of evidence which may be quoted in favour of the use of this new preparation in all forms of syphilis. I propose to analyse these later reports, quoting the earlier works when necessary.

Historical.

Bismuth has been employed as a cicatrising agent in cutaneous lesions since the seventeenth century. In 1786 Odin[2] recommended its use in gastric affections. Masucci[3] employed bismuth proto-iodide for dressing mucous papules, seeking to obtain a local reaction only. Not till 1889 did Balzer[4] make the first experimental tests of toxicity, with a view to the treatment of syphilis by bismuth. These attempts, however, were not successful; the sequelæ observed in dogs by Balzer caused him to abandon the use of the drug. In 1916 Sauton and Robert[5] used bismuth with success in the treatment of spirillosis of fowls. Their experiments were confirmed by Sazerac and myself[6] at the beginning of 1920, and by many repeated trials we proved, in animals and man, the rapid cicatrisant action of sodium and potassium tartro-bismuthate on various syphilitic lesions. These results were verified clinically by Fournier and Guenot,[7] using bismuth in the form of sodium and potassium tartro-bismuthate. It is of interest to follow the results obtained by various workers in different manifestations of syphilis at the several periods of the disease.

Primary Syphilis.

Bernard[8] reported, in several cases of syphilis, three of them primary, the disappearance of lesions in a few days, following two or three injections of several centigrammes of trépol; the treponema frequently disappeared after a single injection. Duhot[9] stated that the action of trépol is rapid and manifest in syphilitic chancre. Truffi[10] noted the regression of a syphiloma, and its rapid cicatrisation, a few days after the first dose. He attributed a powerful spirillicidal action to sodium and potassium tartro-bismuthate. Nicolas, Massia, and Gaté[11] observed rapid disappearance of chancre and cicatrisation in from 8 to 12 days. In nine cases of syphilis treated with bismuth, Pasini[12] observed the rapid disappearance of treponema after the first injection (24 to 48 hours). The drug provoked a very rapid cicatrisation of syphiloma, of which infiltration was more slowly reabsorbed. Induration might persist for several weeks. There is, according to Pasini, a certain opposition between the cicatrisant action and the slower resolvent action. Disease of the glands appeared to be less beneficially influenced; however, the enlarged glands in the neighbourhood of the chancre quickly diminished in size. De Bella[13] treated seven cases of recent syphilis with trépol; according to him, results were steady and lasting, but not rapid. Bismuth approaches more to calomel than to the arsenobenzols. He speaks of the use of bismuth in syphilis as "a great and real acquisition, a new weapon for use against specific infection, a weapon of choice, particularly in those cases showing resistance against or intolerance of other drugs." Define[14] treated seven cases of syphilis (one primary) with sodium and potassium tartro-bismuthate in oily suspension, in doses of 0·2 to 0·3 g., and reported rapid disappearance of the treponema, with early cicatrisation of lesions. Ducrey[15] reported that in patients suffering from primary syphilis bismuth brought about a rapid healing of lesions, even when the latter were much ulcerated; glands disappeared and a huge ulcerated chancre was cured in a fortnight. The treponema disappeared from the surface of the ulcer after the first injection. Berthet[16] agreed with these findings. He found that in primary syphilis, with W.R. still negative (preserological stage), the results obtained up to the date of his communication were encouraging and seemed to indicate that bismuth, like the arsenobenzols, would prove a very useful sterilising agent. Grecho and Muschietti [17] observed that chancre was modified to a degree dependent upon the extent of infiltration and that primary lesions lost their induration; epithelisation and cicatrisation followed. Posadas [18] observed cure of chancres in from four to ten days.

Secondary Syphilis.

Grecho and Muschietti[17] reported rapid disappearance of non-ulcerated mucous patches and of hypertrophic papules, together with slower but evident clearing up of roseola and papular syphilides of iritis. Malignant syphilis was also successfully treated with bismuth, and roseola, papules, and condylomata rapidly cleared up (Bloch).[19] Spillmann[20] observed, in one patient, rapid disappearance of various cutaneous and mucous manifestations following intramuscular injections given every four days over a period of 36 days. Veber [21] reported a case where, after the fifth injection of trépol, a patient suffering from secondary syphilis with specific jaundice, and circinate rash and papular scrotal syphilides, the jaundice cleared up completely. The W.R. became negative after six injections. Jeanselme observed a general improvement after the fifth injection in a patient with febrile secondary syphilis and poor general condition. Pasini[12] stated that the conditions most readily treated with bismuth are mucous patches of the mouth, genital organs, and peri-anal region. He observed cicatrisation of these papules within a few days; hypertrophic papules of the scrotum disappeared in from three to four days. On the other hand, papular infiltrations (papulolenticular and papulo-squamous) appeared to be more resistant to bismuth. Define[14] noted that the W.R., positive before treatment, became negative soon afterwards; he used bismuth with success (sodium and potassium tartro-bismuthate) in cases of persistent headache. Ducrey[15] observed that in secondary syphilis the effect of trépol was a remarkably rapid cicatrisation of mucous patches and condylomata (in 12 days, after the third injection). Spirochætes were destroyed in these lesions after the second injection. In a case of hypertrophic mucous patches of the tonsils and soft palate the latter were healed in a week. Fifteen days sufficed for disappearance of roseola. Truffi[22] found that with this drug secondary manifestations were rapidly cleared up, that a few days after the beginning of treatment spirochætes were no longer found in lesions where they had been very numerous and that the humoral reactions tended to become negative. Berthet described rapid cicatrisation of lesions. Wallon,[24] in a recent communication, stated that mucous papules disappeared most frequently after two injections, and sometimes after the first injection—i.e., in from four to five days of treatment with trépol (in from 5 to 20 days, according to Posadas). With colloidal bismuth, mucous papules became cicatrised, according to the degree of infiltration, in from 6 to 15 days. Using neo-trépol, I have personally observed cicatrisation of buccal mucous papules within four or five days, and disappearance of treponema after the first or second injection. The same effects are obtained in the treatment of hypertrophic papules, roseola, and palmar syphilides. Headache, fatigue, and osteocopic pains frequently cease after the first injection.

Tertiary Syphilis.

Fournier and Guenot[25] reported great benefit derived from the use of trépol in syphilitic periostitis and in cutaneous lesions with encrusted ulcers. They also observed excellent effects in two cases of aneurysm of the aorta. Grecho and Muschietti and Berthet noted very rapid cicatrisation of cutaneous lesions; Fournier and Guenot, and Bloch reported rapid disappearance of gummata. In two cases of tertiary syphilis (crusted ulcers) of the buttock of 12 years' duration and not previously treated, cicatrisation was obtained after seven injections of tartro-bismuthate and one month of treatment. Another case was a chancre-like lesion of the fourchette which became cicatrised after two injections of tartro-bismuthate (Wallon). Bismuth treatment is of great benefit in the specific headaches and general malaise of tertiary syphilis; Ducrey reported cure of an ulcerated gumma of the soft palate in 20 days. Pasini reported excellent results in two cases of tuberous syphiloderma, in two cases of multiple dermo-hypodermic gummata, in a case of gummatous osteo-periostitis of the tibia, and in a case of necrotic osteo-myelitis of the cranial bones. Re-absorption of infiltration and cicatrisation of open lesions was obtained in a month, after from eight to ten injections. Posadas has reported concerning the action of trépol in syphilitic endarteritis. I have seen rapid regression of tertiary lesions as a result of bismuth treatment (trépol and neo-trépol).

Syphilis of the Nervous System.

Various statements testify to the benefit derived from bismuth in treatment of syphilis of the nervous system. Frequently, in these cases, resistance against arsenic has developed, and bismuth has been the more valuable on this account (Hudelo,[26] Milian[27]). Dessert has reported considerable amelioration in acute meningitis and chronic syphilitic meningitis. In two cases of general paralysis mental trouble was clearly relieved, and in one case locomotor troubles were greatly diminished. A. Marie and Fourcade[28] also obtained favourable results. Tixier [29] found a case of heredosyphilis of the nervous system to be distinctly benefited by tartro-bismuthate. Localised lesions benefit most from the treatment. Tabetics suffering from repeated gastric crises, again, are considerably benefited by trépol and neo-trépol.

Serological Action.

Fournier and Guenot were the first to study the action of bismuth on the W.R. They found that whatever the phase of the disease, the reaction was favourably affected; sometimes the latter became negative before the end of the first series of injections. The following are my own results, already reported,[1] in this connexion.

—	Negative.	Partial.	Positive.
Primary syphilis—	Per cent.	Per cent.	Per cent.
Before treatment	8	25	67
After treatment	63	37	0
Secondary syphilis—			
Before treatment	0	28	72
After treatment	90·5	4·5	5

Bloch[19] found that the W.R. was not affected to the same degree as the clinical symptoms. The W.R. is generally rapidly weakened, but almost always requires several weeks, even two months or more, before becoming negative. For this reason Bloch employs bismuth in combination with arsenical preparations. Similarly Sedlak[30] found that combined treatment (trépol and neosalvarsan) results in the W.R. becoming more rapidly negative. Posadas[18] found that with bismuth the W.R. became negative more rapidly than with mercury, less rapidly than with arsenic. Pasini[12] investigated the action of bismuth in the W.R. and Sachs-Georgi reaction, and found it slow and often incomplete. Thus, patients who had left hospital, after having had 10 or 12 injections and a total dose of 2·5 or 3 g. trépol, showed only a lessened reaction, not a reaction completely negative. Wallon[31] showed that the sero-reaction, even when it remained partially positive, was always distinctly bettered. Wallon found the W.R. negative in two cases of primary syphilis treated with tartro-bismuthate. In the secondary period, the reaction was negative 8 times in 16—i.e., in 50 per cent. of cases. With colloidal bismuth the W.R. became negative twice in eight cases.

Sirum,[32] attempting to compare the weights of drugs (bismuth and novarsenobenzol) employed to render negative the W.R. in recently-acquired and active syphilis, found that this process required a mean weight of 2 g. tartro-bismuthate and of 0·5 g. precipitated bismuth or colloidal bismuth (neo-trépol). To obtain the same result, 5·6 g. novarsenobenzol were required. Define obtained a satisfactory result in two cases. Ducrey, on the contrary, affirmed that in all his cases trépol had no effect on the W.R.; this statement, however, does not disprove the anti-syphilitic value of bismuth. It is known, of course, that even with arsenic the reaction does not become negative, in certain cases, until some months after treatment; but no one contests the value of arsenical preparations. From all these results it is clearly too early to state that the W.R. will remain definitely negative after a single treatment with trépol. But it can be stated that from the point of view of its effect upon sero-reaction bismuth is comparable to the most valuable anti-syphilitic remedies.

Bismuth in Cases Resistant to Arsenic and Mercury.

Several writers have commented upon the value of trépol in cases of syphilis recurring after arsenical or mercurial treatment. Fournier and Guenot,[7] for instance, report the clearing up of lesions after three or four injections of tartro-bismuthate. Dessert reported good results in cases resistant against arsenic, and Wallon[24] also, the latter including cases resisting mercury as well as arsenic. Milian[27] obtained, with a fifth injection of bismuth, a cure in a case of long-standing generalised papular syphilides, which had resisted arsenic and mercury. Tixier[29] reported a case of heredo-syphilis of the nervous system, which had resisted arsenic, but was rapidly ameliorated with trépol; Guibert[33] observed a chancre which continued to grow after 6·25 g. neosalvarsan and injections of calomel, but which was cured after eight injections of trépol. Rezende[34] speaks highly of trépol in cases of syphilis resisting arsenic and mercury. Resistance against arsenic and mercury have been frequently observed, and such resistance must also exist against bismuth; Lortat Jacob and Roberti [35] have described a single case—secondary syphilis intensively treated with a bismuth salt. Mucous papules appeared during the treatment; after seven injections of 2 c.cm. (1·4 g.) of the salt on 20 days, the patient was covered with mucous papules in which treponema formicated.* This is the only known case of resistance against bismuth. The latter drug, then, appears superior to other specific remedies, in the light of absence of recurrence, and of its usefulness in cases where arsenic and mercury have failed.

Toxicity, Posology, and Method of Application.

In collaboration with Sazerac I carried out investigations into the toxicity of bismuth in the rabbit. It required 200 mg. sodium and potassium tartro-bismuthate per kg., given subcutaneously, to kill a rabbit; intravenously, only 5 mg. were required. In oily suspension this preparation is no longer toxic; this form—i.e., trépol—is used in treatment. The symptoms which most frequently follow the injection of bismuth are a bismuth line on the gums, grey-blue or slate-coloured, and stomatitis—phenomena reported by Dalche and Viljean[36] as early as 1889. According to the researches of Azoulay[37] and Milian and Perin[38] a deposit of bismuth sulphide occurs in the cells of the dermal connective tissue, principally in the vascular endothelium. From the point of view of prognosis, bismuthic stomatitis is much more favourable than the mercurial form. It is usually found in subjects who take no care of their mouths. Wolfer, making a radiological examination of the gradual absorption of bismuth, found the process to be very irregular.

Bismuth is eliminated (1) by the kidney, (2) by the salivary glands, and (3) by the digestive system. Demelin[39] and others report that bismuth is found in the urine 18 hours after injection of soluble salts, and 24 hours after the injection of insoluble salts. Steinfeld and Meyer[40] found no more bismuth in the urine after 18 hours. Fournier and Guenot[25] found the elimination to be prolonged over 30 hours. According to Pasini[12] bismuth is already in process of elimination in the urine half an hour after injection. The elimination is quantitatively irregular. Ducrey observed bismuth in the urine 26 hours after injection, and remarked that it persisted a long time after the cessation of treatment. Azoulay found bismuth in the saliva 24 hours after the injection of trépol. By the large intestine bismuth is eliminated in the form of bismuth sulphide. Demelin observed bismuth in the bile, blood, and cerebro-spinal fluid.

The insoluble preparations trépol and neo-trépol should be used for intramuscular injection. Injection should be carried out with a 5 c.cm. syringe and a sufficiently large needle, as the liquid is sometimes thick. The most favourable region for injection is the whole of the superior gluteal area Injections should be made alternately into either side, not too close to the site of previous injections. The intravenous route is too dangerous. The dose of trépol should be 2 c.cm. (0·2 g. of the active preparation) repeated every three or four days, until a total dose of 2·8 or 3 g. has been reached. The series of injections should be repeated after an interval of a month, until the W.R. becomes negative.

---

* It may be wondered whether in this case the use of trépol, or better still of neo-trépol, would not have overcome the resistance of the treponema.

Various Bismuth Derivatives.

As I have stated, most workers have used the intramuscular route of injection; the intravenous route has been more rarely used. After numerous experiments with other bismuth salts, I prefer trépol (sodium and potassium tartro-bismuthate) which has given me the best results. Grecho and Muschietti used basic salicylate of bismuth for intramuscular injection, which seemed to them to be better tolerated (3 g. in 20 days) and more active in manifestations of secondary and tertiary syphilis; by the intravenous route they injected bismuth iodide. Bloch, having used bismuth citrate at first, now uses the painless trépol. Soluble tartro-bismuthate was used in glucose solution by Jeanselme and his collaborators. Fourcade experimented with bismuth oxide. Fouard and Wallon tried colloidal bismuth by the intravenous route (bismuth ionoid).

Finally, working with Sazerac[41] I have perfected the preparation neo-trépol, manufactured by Messrs. Chenal and Douilhet, Paris. It consists of metallic bismuth in suspension in a sterile isotonic solution. This preparation contains 95 per cent. of metallic bismuth; it is well tolerated and possesses remarkable therapeutic power in all three stages of syphilis. When neo-trépol is used, buccal symptoms are very rare and pain practically non-existent. At present I prefer neo-trépol to all other preparations; it may be used for intramuscular injections, in doses of 1·5 to 2 c.cm. repeated every three or four days. It is now in routine use at Dr. Fournier's clinic, at the Hôpital Cochin, Paris. Our researches have been confirmed by Barrio de Medina.[42]

Conclusions.

In the light of the above description of the influence of bismuth in syphilis, I feel I can maintain the conclusions published by me in July, 1922.[1] Sodium and potassium tartro-bismuthate and metallic bismuth achieve rapid cicatrisation of syphilitic lesions at all stages of the disease. Although bismuth has only been recently employed, I have every reason to believe that, when used early and in sufficient quantity, it will cure syphilis. The absence of recurrences of the disease, and the effect on the W.R., only serve to confirm this opinion. Equal, from a therapeutic point of view, to arsenical preparations, better than mercurial preparations, bismuth (trépol and neo-trépol) is a valuable antisyphilitic remedy, particularly in those manifestations of the disease which resist the action of arsenic and mercury.

A NOTE ON
SERUM DOSAGE IN DIPHTHERIA.

By CLAUDE B. KER, M.D., F.R.C.P. Edin.,
MEDICAL SUPERINTENDENT, CITY HOSPITAL, EDINBURGH.

A few months ago a Memorandum[1] was issued by the Ministry of Health which very properly emphasised the necessity for the prompt administration of antitoxin in all cases suspected to be diphtheria. Those of us who have had the opportunity of observing, only too frequently, the lamentable results due to late diagnosis and treatment are naturally in complete agreement with the advisers of the Ministry so far as the general principle is concerned. We are, doubtless, equally convinced that far too many lives have been, and are being, lost owing to a want of appreciation on the part of the general practitioner of the importance of early injection and of the grave risks entailed by waiting for bacteriological confirmation of a provisional diagnosis. I am inclined to believe that so far from the situation improving in this respect it is actually worse than it was ten years ago, and I attribute this fact to the unreasonable dread of anaphylactic shock which undoubtedly disturbs many practitioners. So far as the diphtheria patient is concerned I am tempted to agree with a well-known French authority, Comby, that it is a pity that anaphylaxis "ever emerged from the laboratory where it took birth."

Dosage after Provisional Diagnosis.

The question, however, which I wish to discuss is that of dosage. The advisers of the Ministry recommend that a dose of 8000 units should be given immediately in any case provisionally diagnosed as diphtheria. We may admit at once that such a procedure is both safe and efficient. But is it really necessary? Does it not savour a little of the view that one cannot have too much of a good thing? Does it not, moreover, show that lordly disregard of expense which before the war we were accustomed to associate with Government departments? If this dosage is adopted generally the amount of serum used in this country will be certainly doubled, if not trebled, and, as the cost in the long run will fall on the luckless ratepayer, it may not be out of place to consider how far this extra expenditure is necessary.

A minimum dosage of 8000 units suggests a want of faith in the efficacy of antitoxin, which is surely not justified by experience. I do not for a moment imply that large amounts of serum are not often desirable and necessary. In my own practice severe cases are treated with total doses of from 30,000 to 50,000 units, and it is usual to administer at least 16,000 or 20,000 units to patients, who, in addition to faucial lesions, show any sign of laryngeal or nasal involvement. On the other hand, I firmly believe in the efficacy of the small dose for patients suffering from a moderate or mild attack of diphtheria. In support of this view I would refer to the fact that the remarkable fall in the case mortality which followed the original introduction of serum treatment was undoubtedly effected by very moderate and even actually small doses. Later on we certainly obtained better results by increasing the dosage, but the improvement, while sufficiently obvious, was in my experience not nearly so striking. Such a great authority as Baginsky, writing in 1913, recommends doses of from 3000 to 4000 units for cases which we would describe as severe, for instance, infants with laryngeal obstruction. In similar circumstances I would not nowadays venture to give an initial dose of less than 8000 units, and would expect to have to repeat it, but I can remember many cases in old days in which even so small a dose as 3000 or 4000 units proved sufficient.

---

[1] Ministry of Health. Memo. 68/med. Diphtheria.

Scales of Dosage.

There is probably no public body which has taken more active interest in the prevention and treatment of diphtheria than the Board of Health of New York. A circular issued with its antitoxin suggests a scale of dosage for which, no doubt, Dr. William H. Park, the Board's well-known laboratory expert, is responsible. For "mild" cases 2000 to 5000, for "moderate" 3000 to 10,000 units are recommended, and it may be noted that the higher figures refer to adults, the dosage being graduated by weight. Thus from 2000 to 5000 units is considered sufficient for a "moderate" attack of diphtheria in an infant of under two years of age.

My own practice has been to take as a standard a case in which the tonsils are covered with undoubted diphtheritic exudation, but in which there are no other lesions. For such a case 4000 units appear to be sufficient, and this dose is not exceeded unless the patient presents undue glandular enlargement or evidence of severe toxæmia. If, on the other hand, the pillars of the fauces, the uvula, the palate, or the posterior pharyngeal wall are also implicated, an increase in the dose proportionate to the extent of the exudation, is made. For instance, if the pillars on one or both sides are involved in addition to the tonsils the dose would be 5000 to 6000 units; if in addition to that the uvula or palate is implicated it would probably be 8000 units. Cases in which nasal discharge or croup is also present usually receive an initial dose of 10,000 units, and this dose is repeated at 8 or 12 hourly intervals as required. Conversely, if the lesions presented are less extensive and the tonsils are only partly covered or only one is affected a dose smaller than 4000 units may be safely given.

To give a concrete example: A week or two ago a scarlet fever convalescent developed diphtheritic patching on both tonsils, the membrane covering about half the surface of each. Of the clinical diagnosis there was no doubt whatever. The dose given was 3000 units, and by the time the inevitable positive report came next morning from the laboratory the throat was quite clean. Such a result I have found quite common in my experience of post-scarlatinal diphtheria. Otherwise I need hardly say I would not have relied on such a small dose.

Results of a Single Dose in a Series of Cases.

With a view to a possible revision of this scale of dosage I have extracted from my records the results of 1000 cases which received a single dose of 4000 units. From what has been said above it is clear that the vast majority of these patients had tonsillar lesions only, but that the tonsils were well covered. Unfortunately the series contains a small minority who were given 4000 units on other indications. Many of these were small infants with very slight faucial lesions, but apparently ill from other causes and sometimes admitted late in their illness. Of the 11 deaths which occurred in the 1000 cases in the series more than half fall into this group, no less than six being definitely attributed to bronchitis, pneumonia (2), pyelitis, meningitis, and congenital syphilis. The remaining five deaths were probably due to diphtheria, one in particular being due to heart failure following palatal paralysis. The patients were in all cases admitted late, from the fifth to the eighth day of illness, and it is extremely doubtful whether larger doses could have affected the result. While it is natural enough to regret that any fatal case of diphtheria should have received so small a dose, a loss of only five patients out of over 900 suffering from unquestionable clinical diphtheria involving both tonsils does not suggest that small doses of serum are inefficacious. The paralysis-rate in this series was exactly 1 per cent.—that is to say, that 10 patients developed paralysis, which in every case except one was limited to one situation, usually the palate. The remaining patient suffered from sixth-nerve paralysis also.

It must, of course, be understood that, while this series of patients received a single dose only and did not in my judgment require more, a certain proportion of the individuals who get an initial dose of 4000 units will undoubtedly need a second injection, given either in the rare instances in which definite extension is noticed after the first dose, or, more commonly, for the persistence of the lesions. As my ward books only show the total dose, and it would be necessary to hunt through the charts of many years to trace all the patients who, during the period covered by the 1000 single-dose cases, required further treatment, I must content myself with the records of the last few years.

Of the last 377 cases which received an initial dose of 4000 units only 44, or 11 per cent., had second injections. Of these three terminated fatally, two of the patients having been admitted on the fifth and sixth day of their illness. Paralysis occurred on five occasions. I am willing to concede that these results might have been better, if only slightly better, had these patients received 8000 units on admission. Nevertheless, on looking over the above figures I would submit that on the whole the dosage employed has been justified.

It would be possible, were it worth the trouble, to produce a similar series of cases treated with 3000 units only. It would probably show neither deaths nor paralyses. This dose has usually been given for one tonsil well covered or for follicular lesions on both tonsils. Some of the cases, however, were little more than bacteriological diphtheria. Still, I presume it is for these, as being doubtful or suspicious, that the Ministry recommends 8000 units. It may be added that, although thousands of cases have been treated with doses of 1500, 3000, or 4000 units only, I have never seen extension to the larynx occur in a patient admitted with the larynx free. In the days before antitoxin our experience was very different, and I think this record is strongly in favour of the efficacy of relatively small doses.

Conclusion.

In conclusion, large initial doses are certainly necessary for severe cases. For mild and moderate attacks the small dose may be relied on. Those of us who have to consider the price of antitoxin and to contemplate an annual serum bill of perhaps £600 or £700 cannot put the question of economy entirely on one side. If a small dose can reasonably be regarded as sufficient we have no right to expend public money unnecessarily. It is mainly for this reason that I have ventured to raise this question. But I find that some of the medical men in charge of small fever hospitals have been disturbed by a Memorandum which suggests that a system of dosage with which they have been quite satisfied is radically wrong, and I also feel that I should defend methods which have been taught to all my students over a long period of years, and which I see little reason to alter. My chief complaint against the general practitioner, however, is not that, when he is waiting for a bacteriological report, he gives too little antitoxin, but that he gives none at all. If he gave only 2000 or 3000 units as a routine every time he thought it advisable to take a swab I believe there would be a phenomenal fall in the case-mortality of diphtheria.

SYPHILIS AND MARRIAGE.*

BY AMAND ROUTH, M.D., F.R.C.P. LOND.,
CONSULTING OBSTETRIC PHYSICIAN TO CHARING CROSS HOSPITAL.

THE association of syphilis and marriage is the cause of more individual, social, and national trouble than any other disease affecting family life. Obviously, syphilis and marriage should never be associated, and yet, though this is realised by health authorities, doctors, and legal experts, it is only beginning to be realised by the State and by the nation at large.

Prevention of Infected Persons from Marrying.

The difficulties, therefore, which doctors experience when they try to prevent a syphilitic patient from marrying are largely due to the absence of general education on the subject, to the inadequacy of the law of libel to protect them, and to the absence of legal penalties for one person infecting another. Sex knowledge and hygienic education on sexual subjects are doing much to enlighten parents as regards the risks which their children run, especially their daughters, if one of them should marry a person who has previously contracted a venereal disease, and they try to satisfy themselves regarding their proposed son-in-law's fitness for marriage, perhaps getting his doctor to reassure them on the subject.

What can a doctor do to prevent his patient whom he is treating for syphilis from marrying? He can, of course, take an early opportunity to warn his patient that he should not marry till he is, in the doctor's opinion, safe from infecting his proposed partner and their offspring. This warning may, even with intensive treatment, involve a delay of two years before marriage would be safe, and the patient, though very impatient, will usually accept the advice. But this is not always so.

What should a doctor do if he hears that his patient, still in an infectious stage, is going to get married? The Royal Commission on V.D., pp. 56 and 57, Final Report (par. 203), states: "We are informed, however, that a question of much difficulty arises where a practitioner is aware that the advice given to his patient will not be followed and that the marriage will probably proceed."

Professional Confidence.

In such circumstances a doctor cannot, without breach of professional confidence, warn the intended partner, or his or her parents, of his patient's ill-health; and in addition to such a warning being a breach of professional confidence, it would, if in writing, be a libel, if by word of mouth a slander.

The Royal Commission stated that "in a civil action proof of the truth of the defamatory words affords a complete defence, and in criminal proceedings, if the jury found that the defamatory words were true in substance and in fact, and that it was for the public benefit, the defendant would be entitled, under Lord Campbell's Act, to judgment in his favour" (par. 204). The Royal Commission continues, however, "any allowance of costs would usually be a very inadequate compensation for the loss of time and for the trouble caused even by a successful defence." The Royal Commission concludes (par. 205) by saying that "a change in the law in this respect is much needed," and added "that such a communication made *bona fide* should be deemed to be a privileged communication." I cannot find that any change in the law has been made.

"Privileged" Communications.

Dr. Edwin Smith, lecturer on forensic medicine at St. Thomas's Hospital, barrister-at-law, states[1] that amongst the communications now held to be "privileged" are those "made by a doctor to a husband concerning his wife, or to a wife concerning her husband, for the doctor is then immune from legal liability." Dr. Smith adds that "though legally on safe ground, such a communication may be highly indiscreet." Obstetricians and general practitioners are often up against difficulties of this type. The treatment by injections of salvarsan, now indicated for a pregnant woman after previous syphilitic stillbirths, is much more difficult to explain to a wife than when mercury alone was given. I am sure that from the obstetrician's point of view it is much wiser for him to explain the position to the husband, and try to get him to give such information as he may deem advisable to his wife as regards the need for the treatment indicated; for with the knowledge that now exists regarding the causes of stillbirths, and the modern treatment of syphilis, she would not long remain in ignorance of what is happening.

The Need for Treatment Till Cured.

Another difficulty which occurs during the treatment of patients, whether hospital or private, whether married or unmarried, is the frequency with which they cease treatment before being cured. If you hear that such a patient who has ceased attendance is going to marry, and you know that a cure has not been obtained, the fact that he has ceased to be under your care does not alter your position as regards breach of professional confidence. It would make any interference on the doctor's part more difficult. As a gynæcologist, I am only consulted by women, and if it is a young woman of mature age, she usually expects to be treated without her condition being revealed even to her mother. Since the modern treatment of syphilis has come in I never treat such cases myself, but I expect venereal experts will agree with me that a woman, even more frequently than a man, will cease attendance after the local and skin evidences have abated, and you cannot write and endeavour to retrieve her for fear of the letter going astray.

Notification of Syphilis.

Notification of syphilis would make the prevention of venereal marriages more possible, and would more easily ensure the continuance of treatment till cured, and would also make the means for the retrieving of a patient more likely to succeed. But compulsory notification, even if impersonal, would lead infected persons, especially young women, to postpone consulting a doctor; and if the symptoms have abated early, as they often do in women, they will ignore the need for treatment altogether. In Australia and U.S.A., where notification has been compulsory for some years, the proportion of cases ceasing attendance before being cured is from 12 to 19 per cent., and of these 44 to 59 per cent. have been retrieved. The difficulty of enforcing attendance in these cases is sometimes very great, and in some cases, as the Royal Commission stated, "it involved compulsory detention and would work unequally and chiefly upon those who had brought themselves under restraint." Compulsory notification, without compulsory treatment till cured, would not be of much use.

Health Certificates.

If health certificates before marriage were legally required from both intending partners the doctor's difficulties would be much lightened. There would be but little national resistance to getting this done to avoid marriage in cases of possible tuberculosis, heart disease, mental instability, alcoholism, or drug-taking, but compulsory health certificates would be difficult to get legalised and adopted as regards venereal disease. Indeed, it is just because venereal disease would have to be one of the conditions to be inquired into, and, if need be, investigated, that any form of compulsion in this direction is precluded from adoption, for it would often be impossible to examine young girls, even if local soreness, pruritus, or a discharge was admitted. It would sometimes also be difficult, even with the present tests, to determine whether a man or woman previously infected, especially if treated by someone else, is free from infectivity and fit to marry. Sooner than face such a test many a couple would remain unmarried or would migrate to a locality where compulsory notification or health certificates are not in force. The Royal Commission on Venereal Disease realised the difficulty of arranging for health certificates for marriage, and considered that "it would not be possible at present to organise a satisfactory method of certification of fitness for marriage."

---

* A paper read before the Medical Society for the Study of Venereal Diseases on March 23rd, 1923.

[1] Dr. J. S. Fairbairn's "Practitioner's Encyclopædia of Midwifery, &c." 1921. Pp. 773–4.

I have thought much of how some form of health certificate before marriage could be introduced. One valuable suggestion has been made—viz., that all persons desiring marriage should insure their lives in some reliable and recognised insurance company. The examination required to secure an A1 policy would not necessarily be a proof of absolute health, but if a previous infection had been present there might be a refusal to grant such a policy, and this would lead to further investigation. Such policies could be usefully included in the schedules of marriage trusts. For poor people, who would mainly be panel patients, the nation would have to grant the expenses of an examination and the provision of a policy for healthy couples, but this would involve national expenditure, impossible probably to provide under our present financial circumstances.

In the absence of health certificates being legalised, if a young man contemplating marriage is asked a few tactful practical questions by his fiancée's parents or family doctor, and it happens that he has to admit that he has been infected, it will make him pause and perhaps consult his own doctor again. I have known cases where as a result he has been advised to postpone marriage for two years or so, so as to have other tests and further treatment, perhaps in the interval going abroad on foreign service. This often means that the engagement is eventually broken off, and the woman makes a healthier marriage to another partner.

Syphilis Discovered After Marriage.

I have known many couples, one of whom had been recently infected, who have married with disastrous results. Sometimes the infected partner has been ignorant that he had been infected; sometimes he had been told or thought he was cured; sometimes his wife knew of his previous infection without realising the risk of marriage. Sometimes a man has married after being warned that he is not cured. Such a man would endeavour to avoid infecting his wife by adopting methods which at the same time would prevent the risk of conception. The wife of such a man consulted me because of having suspicions after seven years of marriage. Her husband, who had recently died, had told her that she was not in a fit state to conceive, and had adopted a male contraceptive, and had got his wife to apply a daily mercurial inunction without explanation. She was tested and found to be perfectly healthy, and subsequently married a healthy man and had healthy children.

Matrimonial Laws Regarding Venereal Disease.

In his evidence before the Royal Commission on Venereal Disease in 1914,[2] Sir Samuel Thomas Evans, President of the Divorce Court, stated that if a wife establishes the fact that she suffers from a venereal disease, and that she has been faithful to her husband, she can get a divorce if she can prove that her husband had acquired the disease after marriage, for the infection would be a proof not only of legal cruelty, but also of adultery. If the disease had been acquired before marriage and was conveyed "knowingly or negligently" it would constitute legal cruelty, but not adultery, and the woman could only obtain an order for judicial separation, which, as the Royal Commission states in its Final Report (par. 173), "is a very inadequate remedy, especially in the case of the poorer classes."

Treatment of Syphilis During Marriage.

Before 1905, when the *Spirochæta pallida* and the Wassermann test for syphilis were unknown, it was difficult and often impossible to be sure that husband or wife had been infected; especially as the husband might deny previous infection and might have no clinical evidences of having been infected, while his wife often had nothing definite which could draw attention to a recent infection, no local sore being recalled, and a passing rash being forgotten or ignored. Abortions or dead children or congenitally syphilitic offspring were often in those days the chief or only evidence of marital infection. Inquiries from the husband might reveal that he had syphilis many years previously, that he had been treated carefully and was declared to be cured and able to marry with safety. If clinical evidences of syphilis were present in either of the partners, treatment of both was held to be indicated.

Twenty years ago treatment was by mercury in different forms, and if the husband allowed it, it was easy to treat the mother with pills which she could be honestly informed were likely to make her better prepared for a future pregnancy; or if she were already pregnant or had had abortions or stillbirths she could be easily encouraged to be treated so that these intrauterine deaths should cease. This could be done without making her suspicious of the venereal condition. One such case in 1899 I may briefly state, and it is the type of history which often occurred then.

Mrs. A. B., aged 25, married four years; two abortions and two stillbirths. Both partners wished to have a healthy child. No history of syphilis could at first be obtained and there was no evidence of it in either partner. The stillbirths had not been examined. Three months later I found her six weeks pregnant, and I again interviewed her husband, who admitted having been treated for syphilis over 12 years previously. I put her on pills containing 1/16 gr. of hydrarg. perchlor. t.d., and delivered her of a healthy child at full term. She became pregnant again in eight months, but the husband, being satisfied with his healthy son, refused to further entertain my diagnosis, and she was delivered of a puny child who later developed typical congenital syphilis and died when 5 months old. She became pregnant again and was allowed to take the pills and had another strong healthy child. The parents and both the children are now, I am informed, in perfect health.

In those days, as there was almost always no evidence of infection in the mother, she was only treated during pregnancy. It was thought then that the children had become infected by the seminal fluid infecting the ovum when fertilised, and that the mother might not be herself infected. We now know that if a woman has syphilitic offspring she is herself infected. For this reason, when treatment by salvarsan and its substitutes began, the apparently healthy woman was at first only treated during the pregnancy, as the main point was that the child might be born healthy. This good result to the child was almost invariable. Then later on experience showed that the next child might be syphilitic if the mother was not again treated during her next pregnancy. It was soon realised that the treatment of both the mother and child must be continued after parturition, usually by mercury as well as salvarsan. Some pathologists state that if the mother continues to give a negative reaction to the Wassermann test she need not be treated during subsequent pregnancies. It is, however, well known that the Wassermann reaction of the mother is irregular during pregnancy and not very reliable, for even if positive before pregnancy it may become negative during pregnancy, during the latency of the infection, and for some time afterwards. If no maternal treatment during pregnancy has been adopted, the child may be born negative, but becomes positive after a few weeks if congenital syphilis is about to develop.

In 1914, in my Presidential Address at the Harveian Society, printed in THE LANCET of Jan. 10th, 1918,[3] I drew attention to the probability that during pregnancy the chemical products arising from the trophoblastic action of the placental villi have a controlling influence over the biological activity of the infecting spirochætes, probably by breaking them up into granules, which may remain quiescent and latent during the pregnancy.[4] After pregnancy, when the placental chemicals gradually disappear in both mother and child, the granules if not already devitalised, will sprout and develop into the full-grown spirochæte and syphilis will declare itself. The mother is more likely to be better protected than the separated child, especially if pregnancies are repeated. So long as the fœtus is protected by this granulosing of the spirochætes treatment can be successfully adopted at even the last few weeks of pregnancy and the potential activity of the latent granules will be permanently arrested, probably by their destruction. The latency of syphilis during pregnancy is now generally accepted. Exactly how the spirochæte is rendered latent is not yet known. An earlier stage of the mature organism is also conceded by many.

---

[2] Appendix to Final Report, p. 285, Q. 21,093.

[3] Reprinted by request in Amer. Jour. of Syph., ii., 3, July, 1918.

[4] Noguchi has made between 1910 and 1917 cultures from granules, derived from *S. pallida*, which have later on sprouted and have developed into the mature organism which has retained its infectivity. (Amer. Jour. of Syph., April, 1917, pp. 320–3.).

The pioneers in the treatment of ante-natal syphilis are well known and the results are more startling and the success greater than any could have imagined ten years ago. Almost all children (probably 90 per cent.) thus treated have remained healthy for several years and some have been watched for seven years, and the mothers who have had ante-natal and post-natal treatment also remain negative and have other healthy children.

These results prove conclusively that even if we cannot prevent infected men and women from marrying and having children (for syphilis does not tend to sterilise either men or women), we can, with our present knowledge, by treatment of the mothers during pregnancy, enable healthy children to be born, and by continuing the treatment of the mothers and children after parturition we can, in each such family, almost entirely prevent the occurrence of congenital syphilis. Probably this success would be rendered more certain if the father were also treated. This should certainly be done if his Wassermann reaction is positive, and some experts would consider that the father should be treated in any case where syphilis was clinically present in the offspring, even if his tests were negative, as his seminal fluid may be infective, perhaps by presence of granules only, for the mature organism is stated to be very difficult to find in it.

I wish further research could be made as regards this question of seminal infectivity. After the discovery of the *Spirochœta pallida* in 1905, it was found that the organism was larger than the head of the spermatozoon, and the conveyance of the infecting agent by the mobile sperm was viewed as impossible, and the belief in seminal infection of the ovum in the Fallopian tube or in utero was largely given up. When Noguchi showed that the spirochæte could spontaneously break up into sprouting granules, so small that they could easily be carried by seminal fluid or spermatozoon, the idea was revived. If these sprouting granules are a stage in the life-history of the spirochæte, as I believe, seminal infectivity must be reconsidered as an alternative to infection through the mother's blood. In either case the chemical products, already alluded to as arising at the point where the maternal and fœtal circulations come into contact, appear to be usually able to protect both mother and child from clinical syphilis, at all events during the pregnancy. If all doctors and inspectors of midwives could get their women patients who have a history of abortions and stillbirths or infected offspring put under expert medical supervision, especially if pregnant, so that modern ante-natal and post-natal treatment of mother and child could be adopted where syphilis is diagnosed, congenital syphilis would become increasingly rare.

The treatment of a congenital syphilitic child, begun only after birth when the latent period of syphilis is over, is very unsatisfactory, especially if the Wassermann reaction is positive. Success in dealing with ante-natal syphilis should not, however, allow doctors to relax any of their efforts to prevent marriages of infected adults. The Ministry of Health has appointed a Commission, which is now sitting, to investigate the best methods to be adopted to prevent the spread of venereal infection. I hope the Commission will especially consider what further steps can be taken to eradicate congenital syphilis, by ensuring a more efficient medical supervision of women during pregnancy, and by making expert venereal treatment more generally available when indicated.

A CASE OF
MIDDLE MENINGEAL HÆMORRHAGE.

By A. B. KEITH WATKINS, M.S. Lond.,
F.R.C.S. Eng.,
CLINICAL ASSISTANT, SURGICAL OUT-PATIENTS' DEPARTMENT,
LONDON HOSPITAL.

THE following case combines a number of unusual features. On Feb. 11th, 1922, the patient, a window-cleaner, aged 24, was admitted to the Seamen's Hospital, Greenwich, under the care of Mr. Timbrell Fisher. Shortly before admission he had been picked up beside his broken ladder. Subsequent evidence showed he had fallen from a first storey window.

Condition on Examination.—On admission at 10.50 A.M. he was semi-conscious. When told in a loud voice to do so, he would perform movements such as putting out his tongue or bending a limb. He was pale and clammy; pulse 60; temperature 97° F.; respiration 32. A hæmatoma in the left orbit pushed the globe downwards and outwards and a subjunctival hæmorrhage was present. On the right side there was a small hæmatoma in the temporal region. The pupils were small and equal, and reacted to light. No signs of paresis, spasm, or difference in tone of the two sides of the body were detected. There had been no vomiting or external hæmorrhage. A diagnosis of concussion with probable fracture of the anterior fossa was made. At 12 mid-day no change was noted except that from the nose there had escaped a small quantity of blood which appeared more dilute than normal. At 2 P.M. the patient was deeply unsconscious and had vomited once. The tongue was falling back into the pharynx, causing respiratory obstruction; to relieve this it was transfixed and held forwards with a suture while the examination was continued. Respiration was now noisy and stertorous. The left orbital hæmatoma had become tenser, while the right temporal one had increased to several times its previous size and had become very tense. The right pupil was widely dilated and fixed, while the left was small and reacted to light. It was thought that the left side was more atonic than the right, but there were occasional spontaneous movements such as flexion and extension of all limbs. A diagnosis of right-sided compression (probably due to a middle meningeal hæmorrhage) was made, and the patient was prepared for operation. At 2.20 respiration was not so powerful and was definitely of the Cheyne-Stokes variety, there being periods of complete apnœa up to 20 seconds. The left pupil had commenced to dilate, but was still smaller than the right. At 2.30 periods of complete apnœa were present up to 30 seconds. The pupils were widely dilated, the right being only slightly larger than the left, and neither reacting to light.

Operation.—No anæsthetic was used. A U-shaped right temporal flap, including temporal muscle, was turned down, when a vertical fracture was exposed in the anterior part of the wound. A ¾-inch trephine circle was elevated at 1½ inches behind the external angular process and a similar distance above the zygoma; much fluid blood escaped, and the patient at once began to breathe more deeply. The opening in the skull was enlarged with rongeur forceps and much recent clot evacuated. The anterior branch of the middle meningeal artery was found running on the dura and not in a bony tunnel. Alarming arterial hæmorrhage now took place deep in the anterior inferior part of the wound. To get at the site of this the zygoma was quickly divided in two places, and the opening in the skull enlarged downwards. However, the hæmorrhage was so free that even with rapid swabbing nothing could be seen in the depths of the wound, so temporary gauze packing was inserted and the right external carotid tied. The hæmorrhage now ceased. At the end of the operation the patient was breathing deeply and there was no sign of Cheyne-Stokes's respiration. While the skin sutures were being inserted it was necessary to restrain the patient's movements.

Four hours after operation he became deeply comatose again, Cheyne-Stokes's breathing became marked, the pulse rose to 160, and the temperature to 107°. The pupils were equal and no localising signs were found. Soon afterwards the patient died. It was thought that the cause of death was acute cerebral œdema.

Post-mortem examination showed a fractured middle fossa with extensions into the vault. On the right side the fracture had passed through the foramen spinosum, where the middle meningeal artery was found lacerated. No fracture of the anterior fossa was present, but on the left side the fracture had passed through the great wing of the sphenoid, involving the outer wall of the orbit. The dura was intact, but on the right side was separated from the skull over an area of 3 inches by 4. On the left side the dura was separated from the skull by a clot 3 inches by 3. Apparently this had come from the anterior branch of the left middle meningeal artery, for there was an ecchymosis ¼-inch diameter in the dura at the site where this branch of the artery and the fracture crossed one another. The clot weighed 2½ oz. No laceration or contusion of the brain was present, but there was a small subdural hæmorrhage at the right temporal pole.

Interesting Points in the Case.

1. *Bilateral Hæmorrhage.*—Rare cases have occurred. In 1750 J. Hill[1] removed 2–3 oz. of blood-clot from the right extradural space of a young man, and three days later a similar amount from the opposite side. A fracture was seen at each operation. In 1751 he[2] operated upon another man, aged 30, for right middle meningeal hæmorrhage. About 6–7 oz. of blood escaped; four days later the patient was worse and the other side was explored, where another 6–7 oz. of clot was found and removed. Both cases recovered, though the former patient was "sometimes liable to convulsive twitches, but they did not deprive him of his senses; and his memory at times failed him so far as to make him at a loss for words to express himself." Nathaniel Ward [3] has recorded the case of a man, aged 40, admitted to the London Hospital in 1854 under the care of Mr. Luke. Operation for right middle meningeal hæmorrhage was performed, and the patient improved for a time, but died 14½ hours after the injury. Post-mortem examination showed symmetrical detachment of the dura with a large clot occupying the space on the left side.

2. *Laceration of the Artery at the Foramen Spinosum.*—I can find details of only one other case. In 1902 Harvey Cushing[4] operated upon a young man of 24 for middle meningeal hæmorrhage of rapid onset. One hour before admission a beam had fallen upon his head; there was bleeding from the nose and both ears, but no concussion, and the patient stood up and answered questions. Half an hour later he was unconscious. On admission there was slight exophthalmos and the left pupil was larger than the right. During the next hour the stupor deepened, Cheyne-Stokes breathing occurred, and ptosis of the left eye became more marked. Operation was performed through an osteoplastic flap and the middle meningeal artery was dealt with at the foramen spinosum, into which the fracture was seen to pass. Unfortunately we are not told how this was done. It must have been difficult, especially as a skull tourniquet was in situ the while; also, hæmorrhage was probably severe, as the blood pressure was 250 mm. Hg. This case recovered.

3. *Ligature of the External Carotid Controlled the Hæmorrhage.*—It is well known that ligation of the external carotid will not stop hæmorrhage from its branches with certainty, although ligature without craniotomy has been advocated as a treatment of early middle meningeal hæmorrhage. In 1877 Howse[5] tied an external carotid after unsuccessful ligature of several branches of the middle meningeal artery. This stopped the hæmorrhage, but the patient died 16 hours later. Contusion of the brain was found post mortem.

4. *Orbital Hæmatoma may be due to Fracture of the Middle Fossa.*—The majority of orbital hæmatomata after fractures of the skull are due to fractures of the orbital plate of the frontal bone. When one considers that the great wing of the sphenoid, which forms part of the middle fossa, also forms part of the outer wall of the orbit, one cannot but be surprised that orbital hæmatomata are not commoner in fractures of the middle fossa. Marcus Beck[6] reported the case of a patient, aged 25, who was admitted to University College Hospital in 1877 with bleeding from the nose and a subconjunctival hæmorrhage supposed to be due to a fracture of the orbital plate of the frontal and cribriform plate of the ethmoid. There was also a left middle meningeal hæmorrhage. The patient died, and the fracture was found to pass between the foramen ovale and the foramen rotundum on one side through the sella turcica and through the great wing of the sphenoid on the side of the orbital hæmatoma.

Hyperpyrexia.—Considering its importance, little prominence has been given to a raised temperature as a symptom of acute extradural intracranial compression, whereas the occurrence of a low temperature in chronic compression is widely known. Cushing, in Keen's "Surgery," does not mention its occurrence. Trotter, in Choyce's "Surgery," mentions only unilateral raised temperature. Quervain[7] states that a high temperature points more to an intradural than to an extradural hæmorrhage. On the other hand, Wiesman[8] and Thomson and Miles give a rising temperature as a symptom of middle meningeal hæmorrhage. Rose and Carless mention that hyperpyrexia may occur when extradural hæmorrhage extends to the base. In middle meningeal hæmorrhage it is usual for the temperature to be low during the stage of concussion, but it rises progressively during the stage of compression. I have seen a similar rise due to acute extradural hæmorrhage from a lacerated superior longitudinal sinus. In Jacobsen's[5] series of 70 cases of middle meningeal hæmorrhage, hyperpyrexia was commoner where there was greater damage done to the skull. What the raised temperature is due to is not clear. Certainly it occurs in cases where there is no clinical evidence of injury to the pons, and where no sign of macroscopic injury to the pons or basal ganglia is found post mortem.

In conclusion, I wish to express my indebtedness to Mr. Timbrell Fisher for permission to publish this case.

Clinical and Laboratory Notes.

A CASE OF

ACUTE BILATERAL SUPRARENAL HÆMORRHAGE.

BY A. G. MILLOTT SEVERN, M.D. BRUX.,
D.P.H. CAMB.

ACUTE non-traumatic hæmorrhage of the suprarenal bodies is an infrequent pathological occurrence presenting some features of interest, and only a few cases have been recorded. The condition has rarely, if ever, been diagnosed before death; slight hæmorrhage or congestion of the suprarenals is sometimes found in the course of autopsies in the event of death from other well-defined diseases. Children are more often affected than adults, and Arnaud has recorded a small number of cases occurring in new-born infants.

One or both of the suprarenal glands may be involved, and in acute cases the signs are those of insufficiency of the specific internal secretion. In a case reported from America the *Streptococcus hæmolyticus* was isolated from the blood both ante mortem and post mortem, and it was supposed that this organism was the exciting cause. Kempf describes in detail two rapidly fatal cases of suprarenal hæmorrhage in young children, accompanied by a diffuse purpuric cutaneous eruption, pyrexia, and signs of acute infection. The following case came under my own notice.

A single woman, aged 59, a patient in the Devon Mental Hospital, was suffering from chronic melancholia. General condition had been poor during her three years' residence; routine medical examinations had indicated some degree of arterio-sclerosis and slight albuminuria; she had never shown symptoms of definite illness. Weight at different periods varied between 7 st. 10 lb. and 9 st. 2 lb. No signs of Addison's disease or other tuberculous foci; she possessed none of the external sexual abnormalities associated by some observers with disease of the suprarenal glands.

Rapidly Fatal Attack.—Patient appeared well during early part of day of attack; but rather suddenly collapsed in the late afternoon; she seemed profoundly asthenic; temperature was 102·2° F.; she was put to bed. Face and extremities cold and somewhat cyanosed; radial pulse

126 per minute, irregular, "thready," and almost imperceptible. Very marked flatulent distension of abdomen, and general loss of muscular tone; no vomiting, no apparent pain or localised tenderness. Heart sounds feeble; blood pressure greatly diminished. Her condition grew worse and death took place within three hours.

Post-mortem Examination.—The body showed no cutaneous rash or bronzing, or pigmentation of mucous membranes. On opening the abdominal cavity the colon was found to be very distended, but otherwise normal; the heart, lungs, brain, liver, and pelvic organs exhibited no macroscopic lesions. As far as was ascertained, the sympathetic ganglia and the other endocrine organs were normal, with the exception of the spleen, which was pultaceous and pale. Kidneys showed slight interstitial changes; some hæmorrhagic staining of retro-peritoneal tissue in region of pancreas, but this organ was normal on section.

Suprarenal bodies both distended, oval, dark-red in colour, the size of a small hen's egg. Right suprarenal weighed 37 g., and the left slightly less. They were free from adhesions, separated readily from the kidneys, and showed no signs of tuberculous disease or neoplasm. There was no pus or necrotic tissue present, nor evidence of old inflammation. On section the cortex was seen to be thinned and the gland distended with unorganised blood-clot; the medullary chromaffin cells appeared to have been destroyed. The hæmorrhage evidently commenced in the medullary tissue and may well have coincided with the initial syncopal attack.

Microscopic examination of both suprarenal glands showed recent hæmorrhage in medulla causing complete disorganisation of the cells, and the thin cortical layer was infiltrated with blood. Sections were stained for micro-organisms without result and Gram's staining showed no evidence of bacteria.

This case is remarkable in its abrupt onset, the rapidity with which death took place, and the difficulties presented in the way of diagnosis.

I am indebted to Dr. R. Eager, medical superintendent of the Devon Mental Hospital for permission to publish the case.

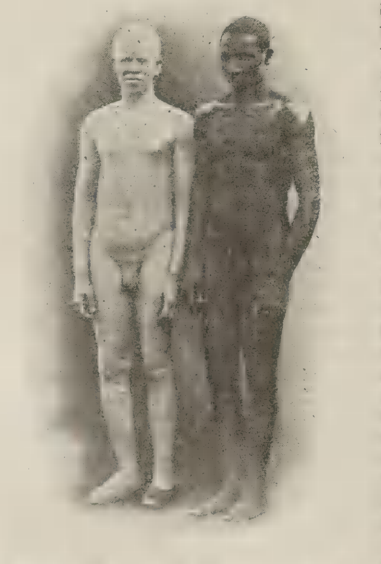
A SUDANESE ALBINO.

By H. E. S. Stiven, M.D. Camb.,

PRINCIPAL MEDICAL OFFICER, GOVERNMENT HOSPITAL, PORT SAID.

The accompanying photograph shows an albino, aged 25, admitted to the Egyptian Government Hospital at Port Said for a sequestrum of his right tibia. The man standing by him is his cousin. He states that his father and mother are typical black Sudanese, and come from Karma village, Markaz Argo, Dongola Province, Sudan. There are no relatives of his mother of abnormal colouring as far as he knows. His father by another wife had normal black children. He had one sister, who died at the age of 18, and one brother who died at the age of 12 white like himself. His eyes are hazel brown, hair on head and body fair flaxen colour, and his skin perfectly white all over the body but of a curious thick texture.



Sudanese albino and his black cousin.

ROYAL SOCIETY OF MEDICINE.

SECTION OF ELECTRO-THERAPEUTICS.

The Movements of the Gastro-Intestinal Mucosa.

At a meeting of this section held on March 16th, with Dr. **Robert Knox**, the President, in the chair, Prof. **Gösta Forssell** (Stockholm) read a paper on this subject. The folds of the mucous membrane of the stomach were, he said, generally supposed to be caused by passive folding of the mucosa as a consequence of the contraction of the muscular coat. The origin of the folds of the mucous membrane of the intestine was explained in the same manner, except that here the folds were supposed to be permanent anatomical structures (the Dauer-falten of German authors). The speaker held that this general view was incorrect and that the folds of the gastro-intestinal mucosa were formed by active movements of the mucous membrane itself. By means of several series of radiograms of the stomach, of the duodenum, and of different parts of the small and large intestine after an opaque meal or enema, he demonstrated that the same part of the stomach or intestine, although retaining the same external diameter, was able to vary the number, position, and pattern of its folds. By direct observations and serial photographs of the exposed mucosa of the ileum and colon in patients suffering from intestinal fistulæ (which were shown at the meeting) great fluctuations of the relief of the mucosa independent of contraction of the muscular coat were demonstrated. Anatomical

Descriptions of Illustrations.

(*See opposite page.*)

Fig. 1.—Two radiograms of a normal stomach, taken at an interval of one minute in an unchanged prone position. Compare the contours of the greater curvature in its upper half, where the mucous membrane shows deep folds; it will be observed how the folds of the mucous membrane have changed their number as well as their position and form, without any change in the width of the stomach.

Fig. 2.—A series of transverse sections (I., *a*, *b*, *c*, *d*, *e*) of the lumen of the stomach, drawn from anatomical preparations, and showing how the lumen of the stomach with the same width of the muscular coat can vary considerably through different folding of the mucous membrane, with regard to the form as well as to the width of the inner surface of the stomach. Through such forms of contraction of the mucous membrane which are shown here—and many other combinations are further possible—the lumen of the stomach can either be formed into a channel with smooth sides or divided into different canals or systems of fissures between the lamellæ. These can be placed in different ways (II., *a*, *b*, *c*, *d*), so that a filtering or sorting of the contents can take place, or small parts of the contents may be completely enclosed by mucous membrane in small digestion chambers.

Fig. 3.—Two pictures of a high jejunal loop (*ab*), taken at an interval of one minute. Observe specially the area marked *a*. In the first picture there are in this area a few wide, simple and deep folds; in the second there are numerous close-set, small folds, dividing the lumen transversely into fine chambers.

Fig. 4.—Showing, above, a longitudinal section of an intestinal loop where a number of different forms of simple mucous contraction are schematically outlined, and immediately beneath it, cross-sections of these varying folds: (*a*) Indicates a fully free lumen, the loop forming an even tube; (*b*) a fold forming a valve to restrain the flow of the chyme; (*c*) and (*d*) folds forming bigger closed digestive chambers; (*e*) a separator-like formation, filtering the contents between the folds. The lower half of the figure shows a longitudinal section of an intestinal loop, where folds are refolded and in close contact with each other with corresponding cross-sections (taken at *e*, *f*, *g*, *h*) beneath. It is clear that by this complicated folding the intestinal contents are divided up in very fine digestive chambers surrounded by mucous membrane; the folds may fill the lumen entirely. All these forms of contraction may be found in radiograms of the living subject.

Fig. 5.—Showing three transverse sections of a strongly contracted sigmoid flexure. In the topmost section a muscular septum, originating from a transverse contraction of the muscular coat, fills the lower half of the lumen. On the other hand, the folds of the mucous membrane fill the remaining cavity in such a way that the section resembles a transverse section of the jejunum.

Fig. 6.—Radiogram of a strongly contracted sigmoid colon. The folds of the mucous membrane dominate the picture, as in the anatomical preparation shown in Fig. 6.

RADIOGRAMS ILLUSTRATING PROF. GÔSTA FORSSELL'S PAPER ON THE MOVEMENTS OF THE GASTRO-INTESTINAL MUCOSA.

Legends to the Illustrations are given on the opposite page.

preparations of the human digestive tract, hardened by the injection of formalin shortly after death, showed similar patterns of the folds of the mucosa to those seen in the radiograms of the living subject. Even the duodenal bulb, which was generally described as being devoid of folds, showed a highly varying relief of the mucosa in both radiograms and anatomical preparations.

Mechanism of the Movements of the Mucosa.

Prof. Forssell concluded from these observations that while the muscular coat (muscularis propria) of the intestine produced the well-known changes of width and external form of the digestive tube, it had no influence upon the localised and individual folding of the mucosa which he had demonstrated. The muscularis mucosæ formed the special contractile organ of the mucous membrane; being attached to the mucosa and the submucosa it was able to displace the mucosa in any direction by means of its transverse, longitudinal, and oblique fibres. The mass of the mucous membrane and, consequently, the volume or size of its folds, was regulated by the variation in filling of its vessels, while the pattern—i.e., the number, position, and form—of the folds was determined by the muscularis mucosæ. While the formation of a high and close relief of the mucosa would obviously be aided by simultaneous contraction of the muscular coat proper, a definite degree of contraction of the muscular coat was not necessarily associated with a definite raising of mucous folds; on the contrary, a certain degree of contraction of the muscular coat producing a certain width of the tube, might be associated with a state of the mucosa varying from a total absence of folds to folding in high relief and complicated pattern.

Rôle of the Movements of the Mucosa in Digestion.

According to the present general opinion that the folds of the mucosa were anatomical and stationary, the function ascribed to them was the purely passive one of enlarging the absorbing surface of the gut and of preventing a too rapid flow of the intestinal contents. The speaker held that while movements of the muscular coat determined the rough division and large displacements of the contents of the intestinal canal, it was the movement of the mucous membrane which carried on the extremely differentiated distribution of the food in digestive chambers of varying form and size, and controlled the fine regulation of the rate of flow along the alimentary canal. The knowledge that the folds of mucous membrane were not passive structures, but represented phases of active movement, must involve a new appreciation of their function. The fact that the whole rigid world of folds and furrows thus became alive and governed by independent motor forces might prove to be of great importance in our conception of digestion from both the mechanical and chemical standpoints. The rôle that disturbance of the motor mechanism of the mucosa might be playing in the pathology of the alimentary tract was as yet very imperfectly understood, and many difficulties might occur in working out this problem. The pathological folding of the mucous membrane was not a subject for Prof. Forssell's comments beyond saying that the importance of realising the mucous relief of the intestine was illustrated by the fact that the deformities of the duodenal bulb such as the so-called "defect" and the "retraction" of the bulb, which were supposed to be due to local spasm of the muscular coat were, in his opinion, mainly produced by deep and voluminous folding of the mucous coat.

Discussion.

Sir HUMPHRY ROLLESTON referred to the beauty of the skiagrams and said he had previously regarded the gastro-intestinal mucosa as being much like the skin and capable only of about the same range of movement as the skin possessed in the act of "goose-flesh."

Dr. A. E. BARCLAY had seen the various foldings of the gastro-intestinal mucosa on many occasions without realising their true meaning, for he was hampered by preconceived ideas and by his former teaching in physiology. It must have been the experience of many that if milk or other translucent fluid were injected into the colon in an attempt to increase the bulk of an opaque enema and make it proceed further along the colon, the attempt frequently failed in its purpose. This failure was now easily explained by the valve-like action of the folds which prevented milk from mixing with the enema.

Dr. J. H. D. WEBSTER referred to recent attempts by radiologists to demonstrate duodenal ulcer by direct filling of the crater, and inquired whether, in view of the occurrence of folds in the bulb of the duodenum, it was possible to differentiate between ulcers and natural folds.

Dr. R. W. A. SALMOND inquired whether the variation in the foldings in the stomach might not be due to the varying distension of the organ by its contents filling out the rugæ.

Reply.

Prof. FORSSELL replied individually to questioners. To Dr. Webster he replied that there was a certain radiographic picture generally believed to be diagnostic of duodenal ulcer, showing a deep notch generally held to be the cavity of the ulcer in the duodenal bulb. His own view was that while the deepest part of the notch might well represent the cavity of a small and shallow ulcer, the apparent depth of the ulcer was much exaggerated by a circular rampart-like fold surrounding the ulcer with accessory folds radiating from it. This might account for the success of medical treatment in cases of supposedly large excavated ulcer of the duodenum, as demonstrated by radiography. To Dr. Salmond he replied that while it was impossible to get any folds if the stomach were much distended, any less degree of distension had no influence either on the number or pattern of the folds.

A vote of thanks to Prof. Forssell, proposed by Mr. THURSTAN HOLLAND and seconded by Dr. BARCLAY, was carried with acclamation.

SECTION OF OTOLOGY.

A MEETING was held on March 16th, Sir CHARLES BALLANCE, Vice-President, being in the chair. A discussion was held on

ACUSTICUS TUMOURS.

Dr. F. M. R. WALSHE said that the work of Magnus and Kleijn had shown how complex were labyrinthine activities. The symptoms of a typical case of eighth nerve tumour were progressive deafness, with or without tinnitus. Neurological experience did not favour "irritation" as an explanation of tinnitus, which might last for years. Tinnitus was not a constant symptom of these cases, and even when it occurred it might be long delayed. And it was not always easy to establish deafness as an initial symptom: the patient might not be aware of the fact. With regard to the vestibular division of the nerve, he thought vertigo was the only symptom which could be definitely attributed to this branch. Magnus and Kleijn's work rendered possible an accurate differentiation between cerebellar and labyrinthine defect symptoms. Ataxy in movement, nystagmus, and muscular atonia or hypertonia were found to be cerebellar, not labyrinthine, in origin. Dr. Walshe had not yet met with a case of eighth nerve tumour which had been recognised at the early or "otological stage" of the disease. The next group of symptoms to appear were usually those due to progressive paralysis of function in cranial nerves adjacent to the eighth nerves, and in the cerebellum. The first of these to show signs was, usually, the fifth. Of the irritative symptoms, the chief were not pain so much as numbness, creeping sensations in the skin, &c. The motor division of the fifth nerve was less commonly affected, but in some there was diminution or absence of the corneal reflex. Involvement of the facial nerve was, when present, next in importance.

Facial paresis was rarely, however, profound. Paralysis of the external rectus was relatively common, but it could be regarded as a false localising sign. Sixth nerve palsy was not the result of direct involvement of the nerve by the tumour, but was a general pressure effect, which Cushing attributed to the strangulation of the nerve between the floor of the skull and the anterior inferior cerebellar artery. Symptoms related to the ninth, tenth, and eleventh nerves must be viewed as terminal symptoms rather than as aids to diagnosis; they showed themselves as dysphagia and dysarthria. Symptoms dependent on compression of the anterior part of the lateral lobe of the cerebellum varied in date of onset and intensity in different cases, but were a constant part of the clinical picture of the disease. They were muscular hypotonia on the same side, inability to perform rapidly alternating movements, and a tendency to overshoot the mark aimed at. In the lower limbs this was manifested in a staggering gait and a tendency to lose balance. Affecting the muscles of the head and neck, it caused such symptoms as nystagmus and defective articulation.

In eighth nerve tumours, general pressure symptoms were the result of compression and distortion of the brain stem, which blocked the exit of cerebrospinal fluid from the ventricular system and led to secondary internal hydrocephalus. The results were headache, vomiting, and progressive visual impairment due to choking of the disc. Also the patient's intelligence might be impaired. Generally, pressure symptoms dominated the picture from the onset, and focal symptoms might not fully appear. Dr. Walshe related the history of the case from which the tumour (shown by Mr. F. J. Cleminson) was obtained, to show how much the details could vary from the cut-and-dried symptom-complex usually laid down. This young woman was admitted because of a uterine lesion, with no complaint of anything referable to the nervous system, though she had considerable headache, her visual acuity was reduced, and she was occasionally sick; also she was stupid. There was chronic otitis media, with free ear discharge, and bilateral papillœdema. Among other events she developed a constant paresis of the right lower face. No relief followed a left supra-tentorial decompression, and she died comatose. It was a typical eighth nerve tumour. There was some dilatation of the ventricles and secondary hydrocephalus. In conclusion Dr. Walshe discussed the physiology of the eighth nerve.

The Surgical Treatment of Tumours of the Eighth Nerve.

Mr. WILFRED TROTTER spoke of the necessity for forming a clear conception of the operative problem. The disease consisted of a benign, slow-growing tumour, nearly always single, and it owed its seriousness entirely to its situation, which rendered it one of the most difficult conditions in the whole range of surgery. As its successful removal meant a sudden cure, with very little disability, minute attention to the technique of removal was fully justified. The same applied to the precise anatomy of the part and of the route of entry to the anterior portion of the posterior fossa, in the angle between the pons and the cerebellum. With regard to their behaviour to disease, the cranial nerves were divisible into two groups: the anterior group, made up of the trigeminal nerve, and the auditory and facial; and the posterior group, but these did not come into consideration in an early case. It was also necessary to remember the relation of the tumour to the medulla. The pressure on the brain stem bore more on the pons than on the medulla, so that in the early case interference with the cardiac and respiratory centres was not so likely as later. The advance of the surgeon to the site of the tumour must be through the suboccipital part of the skull. One of the most important pathological features entering into such a case was the pressure exerted on the brain; the occlusion of the central canal of the nervous system caused secondary hydrocephalus, which, by its pressure, was a real danger in the operation. He explained in detail why a decompression operation in these cases was useless. The general rise of pressure in the posterior fossa in the late stages was accompanied by displacement of the cerebellum through the foramen magnum in the form of a cone, which closed that foramen and prevented the escape of cerebro-spinal fluid, so that the pressure was still further increased. Mr. Trotter concluded by giving a detailed account of the steps of the operation and the dangers to be guarded against. He advocated removing the tumour capsule, to prevent a recurrence, and favoured finishing the operation at one stage, two points upon which experts held diverse opinions.

The PRESIDENT referred to some cases of the condition which had come under his care, and to the great help now afforded in the diagnosis of them by X rays. He mentioned the fact that he assisted at some of the first operations in London on encapsuled tumours of the posterior fossa, and that surgery had now become a much more gentle art than it was many years ago. He agreed as to the absurdity of doing a decompression operation for a tumour which was causing internal hydrocephalus. He favoured the two-stage operation for the removal of these tumours.

Dr. GORDON HOLMES agreed with the clinical picture which had been put forward by the openers. He had had a long experience of this kind of case. The first symptoms were weakness of palate, disturbance of function of the vocal cords, dysarthria, and swelling. Sometimes the glosso-pharyngeal and vagus complex suffered most, apart from the auditory nerve. After the eighth, the nerve most frequently involved was the seventh. Hemiplegic and sensory symptoms on the opposite side of the body were very infrequent. In a certain number of the cases there was very little disturbance of tone. He had seen only one case recover after gross removal of the tumour, a case operated upon by the late Sir Victor Horsley many years ago. Of 13 operated cases which the speaker had had in the last year or two, nine were alive and well some time after the operation—most of them six months after, some three or four years after. He did not think complete nerve deafness was present in all the cases that had reached a stage at which a diagnosis could be assured.

Mr. SYDNEY SCOTT spoke from an experience of 45 cases of auditory nerve tumour. Such a growth often invaded the cochlea, and if an attempt were made to remove the tumour in all cases, it would be necessary to take away the labyrinth to make sure that the disease had been eradicated. He had never felt justified in diagnosing auditory nerve tumour until there was almost absolute deafness, a very difficult condition to be sure of, because sounds which had to be used were generally heard by the good ear.

Sir J. DUNDAS-GRANT spoke of the work of Jones on equilibrium and vertigo as an indication of the existence of optic nerve tumours. Jones stated that on the same side as the tumour all the caloric tests were negative, for the vertical as well as for the horizontal canals.

A number of cases of otological interest were exhibited; and Mr. CLEMINSON showed the eighth nerve tumour referred to by Dr. Walshe.

SOCIETY OF MEDICAL OFFICERS OF HEALTH.

A MEETING of this Society was held on March 16th at 1, Upper Montague-street, London, W.C., when the chair was taken by Dr. T. EUSTACE HILL, the President, and Dr. R. J. EWART read a paper on the

Economic Circumstances of the Country as a Whole, and the Various Rates by Means of which Health is Measured.

He first dealt with the profound effect which the course of epidemic diseases has had on the civilisation of the world, and in particular suggested that the industrial revolution of the nineteenth century was dependent upon the control of small-pox. In this connexion he referred to the view that malaria had been fatal to the civilisation of ancient Greece and plague to that of Rome; and he suggested that the introduction of syphilis in the year 1500, by destroying the economic surplus in the Northern States of Italy, was responsible for the termination of the "Renaissance." Various statistics indicative of the progressive economic changes in the nineteenth century were considered, and stress was laid particularly on foreign trade as an index. This was shown to be capable of division into, firstly, a fluctuation measured by percentage unemployment figures in certain trade-unions, and secondly, a regular upward trend measured either by the consumption per head of food and other necessaries, or by the value of real wages. The speaker proceeded to discuss the influence of the economic variations indicated by these curves upon various death-rates, as follows:—

Scarlet Fever.—The change in the epidemiology of this disease, which occurred about 1830, was attributed to the migration of families from town to town, due to industrial necessity and made possible by the construction of railways and other means of transport. This migration resulted in closer admixture of infectious and susceptible persons in the country as a whole, and it was suggested that the high degree of immunity now existing was due to this cause.

Infant Mortality.—Dr. Ewart attributed the high death-rate amongst infants in the later years of the nineteenth century to the deterioration of the milk-supply in bacterial content, due to the increase in the distance over which the milk was transported; and he considered that the fall in infant mortality after 1899 was caused by the replacement of this contaminated fluid by comparatively sterile milk products.

General Death-rate.—The speaker pointed out that this was not affected by fluctuations in prosperity, but was closely associated with the value of real wages. He considered that this was an indication that the Poor-law had been successfully administered so as to maintain the health of the community during periods of trade depression without interfering with its normal economic life. The liberal relief now granted in the way of food-supply he regarded as the main factor responsible for the present favourable state of the public health; but he feared that the methods adopted were interfering with the normal economic life of the community, and that real wages might thereby be reduced, which he predicted would cause an increase in the general death-rate and in that from phthisis.

The PRESIDENT, Dr. F. E. FREMANTLE, and Dr. G. F. BUCHAN discussed the paper, and in his reply Dr. EWART urged the importance of the consideration of such factors as those dealt with in his paper, which were not commonly considered in the reports of medical officers of health.

HARVEIAN SOCIETY.

THE TREATMENT OF DUODENAL ULCER.

AT a meeting of this Society on March 22nd, with Sir CRISP ENGLISH, the President, in the chair, Sir BERKELEY MOYNIHAN introduced a discussion on this subject. The paper is given in full on the opening page of this issue of THE LANCET.

Dr. A. F. HURST, who followed the opener, said that his interest in the subject of duodenal ulcer was awakened by a visit to Sir Berkeley Moynihan's clinic in 1907. In the following year the records showed that duodenal ulcer was beginning to be recognised and diagnosed as a separate entity at Guy's Hospital. The question under discussion was the treatment of duodenal ulcer and particularly whether such an ulcer could be cured by medical treatment, and, if so, whether medical treatment was to be preferred to surgical. Dr. Hurst maintained that duodenal ulcer could be cured by medical treatment alone. He quoted a case sent to him by Sir Berkeley Moynihan in 1909 with an unmistakable duodenal ulcer with hæmorrhage, the patient having refused operation although it was strongly urged. The man was put on treatment (of which particulars were given in circulars distributed at the meeting) and was cured and had remained well with absolute freedom from pain for 14 years. When such a result could be obtained by purely medical treatment where was the necessity for operation for this condition? The effect of gastro-enterostomy was to divert the irritating gastric contents from the duodenum (for radioscopy proved that nearly all of the meal passed through the new stoma in the majority of cases) thus allowing the ulcer to heal. But operation did not cure the inherent diathesis which predisposed to duodenal ulcer; it could not cure the hypertonicity of the stomach, nor the hyperchlorhydria. The persistence of hyperchlorhydria after gastro-enterostomy was, in fact, the cause of jejunal ulcer after that operation, which, in Dr. Hurst's experience, occurred in no less than 5 to 10 per cent. of cases. Such ulcers were much more difficult to cure by medical means than the original duodenal ulcer, and the condition of some of these patients, often after multiple operations, was deplorable. A further unpleasant sequel of gastro-enterostomy, in a small number of cases, was diarrhœa. It was said that operation was imperative for hæmorrhage or perforation, threatened or actual. Death from hæmorrhage was, in his experience, very rare; there was only one such death from duodenal ulcer at Guy's Hospital during the last eight years, and that occurred two days after the operation of gastro-enterostomy. Of the 19 cases of death from perforation only four had symptoms of duodenal ulcer sufficiently definite to warrant a diagnosis before perforation occurred. Dr. Hurst believed that medical treatment would have attained more general success if the septic foci which had such an important ætiological bearing on the disease were more efficiently treated, and he was inclined to ascribe much of the success of Sir Berkeley Moynihan's surgical treatment to the preliminary extirpation of these foci. The scheme of medical treatment he employed, a modification of Sippy's, was not too drastic when the serious nature of the disease was considered. After attending to the septic foci, this treatment must be continued for 14 days after pain, tenderness, rigidity, occult blood in the stools, and deformity of the duodenum as seen by X rays had all disappeared; it was essential that no exceptions be made to this rule, although the patient might feel quite well two or three days after treatment commenced. The after-treatment was directed against the diathesis; when recurrence occurred after this treatment it was, in 19 cases out of 20, the fault of the patient who committed some indiscretion in diet. Pyloric obstruction and hæmorrhage in a very few cases were the only indications for operation, for Dr. Hurst believed that all other cases were curable by medical treatment if the diagnosis were accurate and treatment correct and adequate.

The following is the scheme of medical treatment employed by Dr. Hurst:—

ULCER DIET.

1. Milk 7 oz. every other hour from 8 A.M. to 8 P.M. inclusive. This can sometimes be replaced twice in the day by the same quantity of junket and once by custard. To each milk feed add Mixture 1.
2. Arrowroot, cream of wheat or Benger, 6 oz., with cream, 1 oz., every other hour from 9 A.M. to 9 P.M. inclusive. Two feeds to have red-currant jelly added, and one to be replaced by potatoes or artichoke purée. N.B.—All the above (1 and 2) can be cold or warm, according to taste.
3. Immediately before milk feeds, ½ oz. of olive oil.
4. Immediately before the arrowroot, cream of wheat and Benger feeds, 1 drachm of Mixture 2.
5. Powder 2, to be washed down in 5 oz. of water at 7 A.M., and patient to lie on his right side for 1 hour.
6. Powder 1, half an hour after every feed from 8.30 A.M. to 9.30 P.M. and also at 10 P.M.
7. 10 P.M. Inject subcutaneously from 1/50 to 1/100 gr. of atropine, or given dr. 2 of Mixture 2.
8. An enema on alternate mornings if the bowels are not naturally opened.

9. Wash the mouth out after each feed, and thoroughly clean the tongue by scraping with a spatula morning and evening.

Note.—During the night the patient should have a feed and Powder 1 by his bedside, so that whenever he wakes, whether in pain or not, he can take a feed followed immediately by a powder. This can be repeated as often as he is awake throughout the night.

Powder 1.—Prepared chalk, gr. x.
Bismuth oxycarb., gr. xxx.
Powder 2.—Bismuth oxycarb., oz. ½.
Mixture 1.—Sod. citratis, gr. xv.
Emuls. magnesiæ, ad i.–iv. drachms, the dose to vary according to the state of the bowels.
Mixture 2.—Tinct. bellad., ♏v.–x.
Aq. ad dr. i.

A hæmorrhage should be treated by emptying the stomach with a Senoran's evacuator and washing and with ice-cold water till it returns colourless. Then give powder 1 every 3 hours, but no food for 24 to 48 hours.

INSTRUCTIONS HOW TO PREVENT THE RECURRENCE OF SYMPTOMS.

Avoid alcohol, except if desired later on, a small quantity of light wine or diluted whisky at meals; avoid effervescing drinks.

Avoid all pips and skins of fruit (whether raw, cooked or in jam, and currants, raisins, and lemon peel in cake), nuts and all unripe fruit. For example, an orange may be sucked but not eaten. Currants, raisins, and figs are particularly undesirable.

Avoid all raw vegetables, whether taken alone (celery, watercress) or in pickles or salad; green vegetables must be passed through a sieve and mixed with butter in the form of a purée. Porridge is only allowed if made with the finest oatmeal.

Avoid vinegar, lemon juice, sour fruit; pepper, mustard, curry, chutney, excess of salt; new bread; tough meat, salted fish or meat, pork, made-up dishes, high game; clear or thick meat soup.

Take plenty of butter and cream, and a tablespoonful of olive oil before each meal.

Eat slowly and chew very thoroughly.

Don't smoke excessively. No smoking at all if any indigestion present.

Have some food in the middle of the morning, and on going to bed, and if you wake during the night.

Have your teeth attended to by your dentist regularly every six months.

Take no drugs in tablet form.

If you have the slightest return of symptoms, go to bed for a few days on a milk diet, and do not wait for the symptoms to get serious.

Dr. **ROBERT HUTCHISON** said that while the opener of the discussion (Sir Berkeley Moynihan) had on a previous occasion described himself as a "physician condemned to practise surgery," he (Dr. Hutchison) would describe himself as a "surgeon condemned to practise medicine," since he preferred the direct attack. He admitted that duodenal ulcer could be cured by medical treatment, but he thought Dr. Hurst's treatment was too elaborate. For himself he would prefer to have his abdomen opened twice rather than undergo Sippy's treatment once. Dr. Hurst's view was that the patient must regulate his life to suit his diathesis; Dr. Hutchison thought this was "not good enough" for a man in the prime of life. After gastro-enterostomy it was his experience that the gastric acidity did fall, so that there was no necessity for strict dieting and giving up smoking, nor did an occasional indiscretion in diet cause a return of the symptoms. Dr. Hurst asked his patients to "throw away the very reasons for living in order to remain alive." For his part, Dr. Hutchison considered such medical treatment not worth while, when by gastro-enterostomy the surgeon could cure his patient and guarantee him against the risks of hæmorrhage and perforation. Hæmorrhage, in his experience, was by no means infrequently fatal. Post-operative jejunal ulcer was, in his experience, very rare.

Mr. **JAMES SHERREN** was in general agreement with the opener. He maintained that where the diagnosis of duodenal ulcer was made from repeated attacks and clinched by the test-meal and X ray findings the treatment should be surgical, for perforation and hæmorrhage might, and did, in fact, occur after medical treatment. After operation the ulcer was invariably healed in every case where he had the opportunity of examining the duodenum either at a further operation or post mortem. As regards the type of operation, he had given up the direct treatment of the ulcer ten years ago. Recently he had been giving gastro-duodenostomy a trial in suitable cases. As regards the question of the persistence or otherwise of hyperchlorhydria after operation, he quoted the results of test-meals after operation in 239 cases. In 208 cases the free HCl was almost abolished and there had been no recurrence of symptoms; in 14 cases the acidity remained high, and further symptoms occurred, and in five of the latter further operation was required for jejunal ulcer. He agreed as to the necessity for eradicating septic foci, and pointed out that a possible source of sepsis, the appendix, could only be removed by an abdominal operation. Surgical treatment of duodenal ulcer was the only treatment worth while, and gastro-jejunostomy, he considered, was one of the most brilliant operations in surgery.

Dr. **MORELAND MCCREA** said that as a general practitioner his experience of duodenal ulcer had not been large, yet he had seen several deaths from hæmorrhage in this condition. He had also seen cases in which operation had failed to give relief owing to a septic focus in an antrum having escaped detection. Drainage of the antrum had, in these cases, been curative. In order to improve results the septic foci must be found and dealt with. Before any abdominal operation, he thought it essential that the patient should be overhauled by a physician, and, if it were found that the blood pressure were below normal for the individual, operation should be deferred, as there was a danger of infarction. As regards the anæsthetic, he confessed to a dislike of ether owing to the frequency with which it was followed by patches of pneumonia. The treatment after operation should be left in the hands of the physician. If asked to give his vote, he would record it in favour of surgical treatment.

Mr. **GEORGE WAUGH** pointed out the uncertainty of diagnosis of duodenal ulcer other than by operation as a possible cause of divergence of opinion on the relative merits of medical and surgical treatment. Duodenal ulcer must be a rare disease when the distinguished opener had attracted to his clinic but 500 odd cases in ten years; yet the cases diagnosed as duodenal ulcer were legion. In his own practice he found this a difficult lesion to diagnose; not 1 in 20 cases exhibiting the symptom-complex was found at operation to have an ulcer. What the patient sought was relief from pain, and no evidence had been produced that the ulcer was indeed the cause of pain; while the gut was well known to be insensitive to any form of injury (cutting, crushing, burning, &c.), other than traction on its mesentery, it seemed to be wrong to attribute pain to ulceration. Mr. Waugh quoted a case where pain persisted after gastro-enterostomy and could only be relieved by lying down. At a second operation performed by himself it was found that the duodenal ulcer had healed, but the anastomosis had sloughed, leaving an ulcer with the pancreas and aorta in its base. Yet this patient had been able to eat roast beef without discomfort when lying down! He considered that the ætiological bearing of a septic focus in the production of duodenal ulcer was not proven; it should be remembered that 75 per cent. of the population between 1 and 18 years of age suffered from septic teeth or tonsils, yet duodenal ulcer was a very rare disease between those age-limits. The value of gastro-enterostomy was obvious in some conditions, such as saddle-shaped ulcer of the stomach and pyloric stenosis, or as a sequel to the closure of a perforated duodenal ulcer, but for unperforated duodenal ulcer it was less rational. In 18 of these cases he had dealt only with embryonic mesenteries, with immediate results which were dramatic. Three cases relapsed and began to have symptomless vomiting some months after the first operation. On re-operating he found that the duodenum which had previously been large and distended had shrunk owing to the contraction of fibrous tissue in the healing process. In these cases gastro-enterostomy to relieve the obstruction gave lasting relief.

Sir **WILLIAM WILLCOX** said that our knowledge of duodenal ulcer was largely due to the pioneer work of the opener. He believed that the cause of duodenal ulcer was always sepsis, although such sepsis was not always clinically demonstrable. He urged that where no other focus could be found the teeth should be X rayed; even though they appeared quite sound, apical sepsis would thus often be demonstrated.

Where there was a recurrence of symptoms after a thorough and early trial of medical treatment he advised operation. Hæmorrhage was another indication for operation. He had seen cases die of hæmorrhage, when untreated surgically, and others recover after blood transfusions and operations, although apparently hopeless. On the other hand, he had known patients recover completely, in one case for as long as 17 years, without anything more than simple medicinal treatment, even though they had had severe hæmorrhage.

Mr. IVOR BACK thought it was curious that the anastomosis of an acid-secreting viscus with an alkaline-secreting viscus should produce results which were described as a "glory to surgery." He asked whether we were not dealing with an end-product of disease, and whether by attacking the prime cause it might not in the future be possible to dispense with such operations.

Dr. HURST, in reply, said that although the exciting cause of duodenal ulcer was invariably sepsis, the subjects of duodenal ulcer had nearly always the duodenal ulcer diathesis, often familial, which manifested itself in the hypersthenic stomach and hyperchlorhydria. For this reason constant care was required, although the very strict régime he recommended might be relaxed somewhat after two years. He explained the fact that no death had occurred in his own practice from hæmorrhage from duodenal ulcer by the treatment he employed. It was essential to stop the gastric secretion set up by the presence of blood in the stomach; this he did by washing out the stomach with ice-cold water, leaving sometimes one drachm of adrenalin in the emptied stomach. He allowed no food, but gave alkaline powders every three hours. He was always prepared to do a blood transfusion, but this was only rarely necessary.

Sir BERKELEY MOYNIHAN, in reply, said that duodenal ulcer was not so rare as might be imagined from his figures. He had had more cases in the preceding ten years than in the ten years under review, for there were now a number of other surgeons at Leeds, some of whom had been trained by himself, who operated on a large number of these cases. As regards the relative merits of medical and surgical treatment, he pointed out that the majority, if not all, of the cases in which death occurred from perforation had had one or more courses of medical treatment. As regards diagnosis, he thought that if sufficient care were taken mistakes would only rarely be made. In his last 200 operations the diagnosis had only proved to be wrong on five occasions. In fact, he knew of no disease in which the diagnosis could be made with more certainty. He felt that Mr. Waugh was confusing the picture. Some mobility of the colon was normal, and he knew of cases where colectomy had been performed for duodenal ulcer, and death occurred shortly after from perforation. As regards the ætiology, he could not be certain as to the exciting cause, although he believed that this was invariably sepsis in the mouth, the accessory sinuses, or the abdomen. If sufficient care were taken with each patient it was possible to keep the mortality of surgical treatment to zero, whereas medical treatment had always its mortality from hæmorrhage and perforation. Even where jejunal ulcer occurred the cases could still be cured by gastrectomy, which he had performed as a secondary operation on many occasions, with only one death.

PRESENTATION TO DR. W. W. D. THOMSON.—At a reception given in the Medical Institute, Belfast, on March 22nd by Prof. R. J. Johnstone, F.R.C.S., and Mrs. Johnstone, opportunity was taken to make a presentation to Dr. Thomson and to congratulate him on his recovery from a long and trying illness. The presentation was made by Prof. Johnstone, President of the Ulster Medical Society, who referred to Dr. Thomson's good record as a student, and his services as secretary of the Society. The presentation took the form of a cheque, a silver tray bearing the names of the subscribers to the presentation, and a ring for Mrs. Thomson. Dr. Thomson referred feelingly to the sympathy shown to him by medical friends during his illness.

Reviews and Notices of Books.

ELECTRO-THERAPY.

Electric Ionisation. Second edition. By A. R. FRIEL, M.D., F.R.C.S.I., Aural Specialist, Lissonia and Almeric Paget Ionisation Clinics for Otorrhœa; Aural Specialist, Ministry of Pensions Boards, London District. Bristol: John Wright and Sons, Ltd. 1922. Pp. 132. 8*s*.

THE second edition of this book contains two short additional chapters: one by Dr. Bouchet, of Paris, on the treatment of endometritis by ionisation; and the other by Mr. Ernest Sturridge, on the treatment of pyorrhœa by the same method. The first three chapters of the book deal, as before, with physical principles, apparatus for treatment, and the properties of various ions, while the remaining seven chapters are devoted to the practice of the method of ionisation for the treatment of disorders of various parts of the body. Some account is given of all the ions which are in general use, and of the diseases which can be treated by them, but the author pays chief attention to the zinc ion and its application in cases of infection of wounds, sinuses, the accessory sinuses of the nose, and the middle ear. A complete chapter is devoted to the subject of the disinfection of the middle ear by zinc ions in selected cases of chronic suppurative otitis media. The author states the type of case which should be selected for treatment by this method, gives full details of the methods which he has adopted, and tabulates the results of a lengthy experience. He gives the results of other workers, and a note is contributed by Dr. T. B. Jobson on his experience of ionisation in chronic otorrhœa. The author advises that when treatment by zinc ions is given, dosage should be more accurately measured, and he proposes a new unit for which he suggests the name "leduc" in honour of the distinguished professor at Nantes. This unit takes into account not only the strength and duration of the current, but also the area of the part subjected to the treatment. The adoption of this unit would render dosage more exact in treatment by zinc ionisation. If we may judge from the results of the author and other workers, the value of zinc ionisation for chronic suppurative otitis media would seem to be established.

This book is a useful and practical guide to the subject of ionisation.

An Introduction to Electro-Therapy. By CATHARINE JAMESON, Member of the Chartered Society of Massage and Medical Gymnastics; Qualified Teacher of Medical Electricity for the Society's Examinations. London: H. K. Lewis and Co., Ltd. 1923. Pp. 196. 6*s*.

THIS book is intended primarily for those who are studying for the examination in medical electricity held by the Chartered Society of Massage and Medical Gymnastics. The subjects for the examination are elementary faradism and galvanism, and the author devotes the greater part of the book to the physics, electro-technics, and medical uses of the faradic and galvanic currents. Other branches of medical electricity—viz., high-frequency, diathermy, static electricity, and the testing of the electrical reactions—are considered too briefly even for the purposes of an introduction, and the wisdom of their inclusion in such a manual is doubtful. The descriptions of the construction and working of faradic and galvanic apparatus, and the instructions regarding the application of the currents and the comfort of the patient during treatment, will be useful to the masseuse during her preparation for the examination, but in the elementary scientific principles which must be studied before the subject of electro-therapy can be intelligently grasped the book is frequently at fault; for example, statements are made that the ether conducts waves of sound, that water can be evaporated into its component gases, that a static machine, when running, becomes highly magnetic. The description on p. 54 of the changes which occur in the electrodes is inaccurate in detail, atoms being confused with ions, and there are numerous other errors. The comparison of the movements of ions, and their separation, to the dancing partners in a ball-room is attributed by the author to Leduc, but the analogy was first made by Lewis Jones, and Leduc uses it in his work "Electric Ions and their Use in Medicine," with due acknowledgment to its originator.

THE VASO-MOTOR SYSTEM.

By Sir WILLIAM M. BAYLISS, M.A., D.Sc., LL.D., F.R.S., Professor of General Physiology in University College, London. London: Longmans, Green and Co. 1923. Pp. 163. 7*s.* 6*d.*

THIS excellent, though somewhat technical monograph will form a valuable addition to the literature on the physiology of the circulatory system. It only purports to discuss the various factors which produce changes in the calibre of the blood-vessels; when we see how numerous and complicated these factors are, and when we remember that recent study has shown that contractility is not a monopoly of the arterioles, but is shared by capillaries and to some extent by the veins as well, we can understand that there is much to discuss and not a little on which to speculate, falling within the purview of this volume. Many lines of work and thought focus on to this question of vaso-motor effect, but the author has none the less been compelled at times to be refreshingly desultory. It is seldom that a work of this nature, illustrated by as many as 67 well-produced figures, is offered at such a reasonable price; the last page supplies the explanation, for the monograph was printed in Saxony—and very well printed too.

TUBERCULOSIS.

A Simple Treatment for Tuberculosis. By OWEN F. PAGET, M.D. With an Introduction by J. GEORGE ADAMI, M.D., F.R.S., and Prefatory Remarks by W. P. BIRMINGHAM, B.A., M.D. London: Constable and Co., Ltd. 1923. Pp. 90. 5*s.*

IN his introduction to this book Prof. J. G. Adami speaks with cautious sympathy of the investigations carried out by the author. "I have myself experienced the danger of obsession, and . . . I have . . . a distinct sympathy for one who has had the courage of his convictions. . . ." Of the author's enthusiasm there can be no doubt. The treatment which he advocates consists of the insufflation of dry, powdered tubercle bacillary emulsion (B.E.) into the nose. He gives a fairly full account of the rationale of this treatment, and publishes charts showing how effective it may be in bringing down the temperature. These charts suggest that the temperature fall is not by definite crisis, but it does ultimately come down—"invariably," according to the author. It is natural in a book of this character for the reader to turn first to the results obtained. On p. 39 the author states:—

> "The number of cases of tuberculosis which have passed through my hands since the commencement of my investigations probably reaches 1000. The last series, on which the dosage given is founded, consisted of 500 cases of tuberculosis and suspected tuberculosis, which were under my care when serving with the Australian forces. Every patient improved under treatment, and no patient refused treatment. In my first fortnight before treatment commenced there were three deaths. In the following ten months with treatment there were two deaths, of these one, an advanced case, had old syphilitic disease of the nose, the other had at best a week to live when admitted. He lingered three months."

No one familiar with statistics in general and tuberculosis in particular will be vastly impressed by these statements, and it is a pity that the author has not submitted more carefully analysed material by which readers can judge of the merits of his treatment. It is conceivable that this method of giving tuberculin is superior to the oral, rectal, cutaneous, intracutaneous, subcutaneous, and other methods, and the recent work of Besredka, referred to in an annotation in THE LANCET of Jan. 6th (p. 34), certainly suggests that some of the problems of immunisation may be solved by his theory of "organ receptivity." Though Dr. Paget does not give the impression of having gained a profound knowledge of pulmonary tuberculosis in all its varied wickedness, he is a breezy writer with a light touch. He is no lover of milk, witness his aphorism: "There is only one time in life when man should drink milk, and that is when he is too feeble to be capable of anything else." And again: "I sometimes wonder whether more human beings have not been maimed and killed by drinking the milk of tuberculous cows in our generation than have died from alcoholic poisoning." Who dare say he is wrong?

MENTAL DEFICIENCY (AMENTIA).

Fourth edition, revised and enlarged. By A. F. TREDGOLD, M.D., M.R.C.P., F.R.S.Edin., Lecturer on Mental Deficiency at London University; Physician and Neurologist to Royal Surrey County Hospital. London: Baillière, Tindall and Cox. 1922. Pp. 564. 21*s.*

IN this fourth edition of Dr. Tredgold's well known book alterations and additions are numerous and important, and many new illustrative cases are quoted. The most notable changes are on the psychological side. With regard to amentia in general, while admitting that lower grades show chiefly a failure of attention, perception, or memory, Dr. Tredgold now takes up the position that the essential characteristic of amentia is a "defect of wisdom," meaning by this the faculty first so named by Dr. Mercier, by virtue of which a man can make plans, cope with new situations, take long views, and shape his conduct so as to deserve success in life. As tests of wisdom there are suggested Terman's ball and field test, Healy's construction tests, and the Porteus mazes, but while no one denies that these tests supply evidence of capacity to plan, success in them does not prove any great degree of wisdom. There is no test of wisdom but living, and Dr. Tredgold's criterion is surely too high. Many seriously lacking in wisdom in his sense can make a fair show in a limited environment, sufficient indeed to satisfy Dr. Tredgold's standard of normality—"the maintenance of existence without supervision or support." The section on moral imbecility has been rewritten, and Dr. Tredgold's position in regard to this much-disputed subject is noticeably altered. The distinction between moral perception and moral sense is now made clear, the latter term being reserved for the "emotion concerning right and wrong," the "sense of obligation to do the right and eschew the wrong." In his enumeration of the fundamental human instincts, however, he curiously ignores entirely the "social" or "gregarious" instinct, although in one passage he admits that in some persons altruistic tendencies may be innate and have the compelling force of instincts. For the same reason Dr. Tredgold, while predicating absence of the moral sense or emotion as the most obvious feature of the moral imbecile, maintains his contention that there is also a defect of wisdom. He holds that a moral imbecile is a mental defective whose intellectual defect is not so obvious as it is in the case of those who are usually so designated.

The chapter on clinical examination has been considerably revised and enlarged, and much greater prominence is given to modern tests. Goddard's arrangement of Binet's scale, although only 11 years old, is already somewhat out of date, and might well be replaced by a more carefully standardised revision like that of Mr. Cyril Burt. Dr. Tredgold is not concerned by evidence from tests that amentia shades into normality by gradual stages. He holds that amentia, like genius, savours of the abnormal, and there is certainly much in the behaviour of many aments (and many men of genius) to support this opinion. His experience of the use of pluriglandular extracts in mongolism is interesting, as is also his suggestion, new, we think, to this edition, that there are two types of cretinism, one in which the thyroid lack is but a complication of primary amentia, the other in which the thyroid insufficiency is the fundamental cause of the amentia. This would account for variations in response to treatment. The chapter on causation remains, practically unaltered, as a brilliant example of expert investigation and expert judgment.

It has almost become a platitude to say that Dr. Tredgold has written the standard work in English on this subject. It should be periodically re-read by all concerned with diagnosis or care of defectives. Its lucid style gives added pleasure to the reading.

SEXUOLOGY.

Das Geschlechtsleben des Menschen. By Dr. Placzek. Leipzig: G. Thieme. 1922. Pp. 205. 4*s.* 2*d.*

There being in the English language no compendium of sexuology, but unfortunately many sciolistic and artless productions touching one or other part of the subject, and ignoring the most of it, Dr. Placzek's book might well be translated. For those who wish to become real students it would serve as primer to the important work of Mr. Havelock Ellis, which at last is procurable. By adopting the tabular form, this Berlin neurologist has got into 200 small octavo pages of good print a most serviceable and adequate outline of modern sexuology. There are also some fresh observations—e.g., that in eunuchs castrated early the beard may appear late in life, as it does in old women. Steinach's work and the general deductions therefrom are rated high, although his histological claims are on the whole rejected. Freudism is perhaps not rated quite high enough. The author thinks the evil effects of coitus interruptus exaggerated, especially as regards the male partner. The volume is compact and well thought out.

ST. MARY'S HOSPITALS, MANCHESTER.

A Short History of the St. Mary's Hospitals, Manchester, and the Honorary Medical Staff, from the Foundation in 1790 to 1922. By John Webster Bride, M.D. Manchester: Sherratt and Hughes. 1922. Pp. 132. 6*s.*

St. Mary's Hospitals, Manchester, are now known as St. Mary's Hospitals for Women and Children, Whitworth-street West, and High-street, Rusholme. Their former title was St. Mary's, Southern, and Maternity Hospitals, and they were amalgamated in 1904. The original hospital, which was not known as St. Mary's until 1854, was founded by Charles White, one of the surgeons to the Manchester Royal Infirmary, in 1790. Associated with him were three other medical men, also on the staff of the infirmary—namely, his son Thomas, and Edward and Richard Hall. The hospital was at first housed in what had been a private house in Old Bridge-street, Salford. In 1795 it was moved to another site, the Bath Inn in Stanley-street, and was then known as the Lying-in Charity. In 1840 another move was made to South Parade, St. Mary's, Manchester, but by 1853 accommodation was found insufficient and steps were taken to procure a new building. This was built in Quay-street, Manchester, and was opened in 1856. We do not clearly gather from Dr. Bride's account what was the ultimate fate of the Quay-street Hospital, but in 1904 a new hospital was opened in Oxford-street, Manchester, and the amalgamation with the Southern Hospitals was carried out. This was the gynæcological branch and a maternity branch was opened in Whitworth-street (formerly Gloucester-street). Another branch was opened in High-street in 1912. All this is set out in this short history, as well as a series of biographies of past members of the staff, including such notable names as that of Charles Clay, the father of ovariotomy in Europe. His first ovariotomy was performed on Sept. 13th, 1839. Other well-known names are those of David Lloyd Roberts, Charles Cullingworth, and William Japp Sinclair. The book concludes with an account of the work of the hospitals at the present day.

Altogether a very interesting little book, which would have been still better had the account of the various moves and sites of the original hospital and its successors been made more clear.

DIAGNOSTIC AND THERAPEUTIC ERRORS IN OPHTHALMOLOGY.

Diagnostische und therapeutische Irrthümer und deren Verhütung. Edited by Dr. J. Schwalbe. Part IV. of the Ophthalmological Section by Dr. Bielschowsky, Director of the University Eye Clinic at Marburg. Leipzig: George Thieme. 1922. With 40 illustrations. Pp. 106. 2*s.* 9*d.*

This volume of the series on diagnostic and therapeutic errors, edited by Dr. J. Schwalbe, deals with anomalies in the position and movements of the eyes, nystagmus, disturbances in the normal reactions of the pupil, exophthalmos and enophthalmos, alterations in the visual fields, and finally cerebral and psychic disturbances of vision. It appears to us to give an account of the subjects selected, which is good as far as it goes, but incomplete. No description at all of any operative procedure is included. On the other hand, the indications for and against tenotomy and advancement of the different muscles are given in great detail and with sound judgment. There is very little about the subject of heterophoria and nothing about its diagnosis or about its treatment with prisms, but the illustrations of the various varieties of squint and of the faulty positions of the head caused by muscular paralysis leave nothing to be desired. In the section on perimetry the only method of diagnosing small scotomata mentioned is Bjerrum's—a very good one no doubt, but one that has been usefully supplemented in recent years for the benefit of those practitioners whose consulting rooms are limited in space, and of these newer methods no mention is made.

The volume is easier to read than most German text-books and parts of it contain information not found elsewhere. In discussing the causation of retro-bulbar neuritis, for example, it is of interest to find that in the experience of the author only about 3 or 4 per cent. of the cases are due to affections of the nasal sinuses, and nearly half of the total to disseminated sclerosis, the proportion of cases in which no cause can be assigned being only 10 to 20 per cent. His point is that it may form the sole symptom of disseminated sclerosis that can be detected. Unfortunately we are not told how to differentiate these cases from the rest.

ECTODERMOSES NEUROTROPES.

Poliomyélite, Encéphalite, Herpès. Par C. Levaditi. Monographies de l'Institut Pasteur. Paris: Masson et Cie. 1922. Pp. 269. Fr.24.

The author is to be congratulated upon the issue of this excellent monograph. In his foreword he explains that a large proportion of experimental material in its composition is unavoidable, and is the outcome of a special training which makes him look at things from such a point of view, and put all hypothèses to the experimental test. We feel it is not without legitimate pride that he utters this half-apology. In a generation still disposed too meekly to accept pious opinion from authority, it is refreshing to find one who supplements every statement by experimental evidence: in consequence the book makes most interesting reading, and should be known to every pathologist and physician.

Much of the work upon which the monograph is based has from time to time been noticed in our columns. It embraces a clinical and experimental study of poliomyelitis and encephalitis, and, in addition, a general survey of such conditions, including rabies, herpes, and vaccinia, as affect the skin or the nervous system and are traceable to filtrable viruses. In the portion dealing with poliomyelitis the author had the collaboration of K. Landsteiner; whilst P. Harvier worked with him upon encephalitis. In an interesting theoretical conception it is suggested that there is a closer affinity between the several conditions referred to than has been generally recognised; it is held that the fact that some diseases of this group—such as vaccinia—have a special affinity for the skin, whilst others are partially dermotrope and facultatively neurotrope—e.g., herpes—and yet others are purely neurotrope—e.g., rabies—may be really a point of similarity, since the nervous system is developmentally a derivative of the skin. Such a grouping is strengthened by the kindred characters of the viruses of the diseases, and it may well be that when these are discovered, and capable of examination in pure culture, the grouping which Mr. Levaditi has drawn up will be replaced by a similar one constituted on systemic bacteriology.

The book is sufficiently illustrated, but we notice that the lithographic plates are incorrectly numbered. In his preface Dr. Roux cites this work as an excellent example of the fertility of the Pasteurian method, the author having worthily followed the great traditions of the institute in which he has worked.

PHYSIOLOGY OF THE ASCENT OF SAP.

By Sir JAGADIS CHUNDER BOSE, M.A., D.Sc., LL.D., F.R.S., C.S.I., C.I.E., Director, Bose Research Institute, Calcutta. London: Longmans, Green and Co. 1923. Pp. 277. 16*s.*

THE problem of the ascent of sap in trees is an old one; important work on this subject was done by the Rev. Stephen Hales, whose researches on blood pressure are familiar to most medical readers. But Hales, and many after him, found that the problem of the ascent of sap was not to be solved by such simple experimental methods as were applicable to the investigation of arterial blood pressure. Botanical science waited long for its Ludwig, but at last the master of experimental technique, capable of attacking this and kindred problems materialised in the person of Sir Jagadis Chunder Bose. The apparatus of precision which he demonstrated in this country not very long ago were the admiration of all and the envy of some. It is with especial pleasure that we scan the present volume giving an account of the author's researches. Written in unexceptionable English, and very well illustrated, it is, we feel, destined to become a classic in botanical literature. Whether the author's theories find general acceptance or not, they represent a potent stimulus which experimental botany greatly needs for its development. The researches are the logical sequence of the author's work on the mechanism of plant movement; this he believes to be due to pulsatile contractility of the living cells. The ascent of sap is affected by stimuli and by external changes in the same way, and it is concluded that it also is due to contractile phenomena.

A MANUAL OF DENTAL ANATOMY.

Human and Comparative. Eighth edition. By Sir CHARLES TOMES, LL.D., F.R.S., F.R.C.S. Edited by H. W. MARETT TIMS, O.B.E., M.A., M.D., with the assistance of C. BOWDLER HENRY, L.R.C.P., M.R.C.S., L.D.S. London: J. and A. Churchill. 1923. With 325 illustrations. Pp. 547. 18*s.*

THE eighth edition of Tomes's Dental Anatomy follows on much the same lines as its predecessors, but there are some important modifications. The name of Prof. Hopewell-Smith has disappeared from the title-page; Dr. Marett Tims, assisted by Mr. Bowdler Henry, is responsible for this edition. The book has been considerably shortened by the use of smaller type, but it is hardly so pleasant to handle or to read as the previous edition. A noteworthy feature is the increased space given to the naked-eye anatomy of the human teeth. Some admirable drawings, the work of a student at the Royal Dental Hospital, accompany them. A dental student should know the anatomy of the teeth at least as well as a medical student should know the skeleton, for there is hardly a branch of operative dentistry in which such knowledge is not of importance. With the extension of the curriculum required for the L.D.S. comparative dental anatomy has receded somewhat in importance—we trust that it will never be abandoned—and in its place a more extensive knowledge of the human teeth is required. Hitherto there has been no modern text-book in this country which has dealt adequately with the shapes of the teeth of man, so that the account in this edition is doubly welcome. Indeed, we could wish that it was even fuller, for there are many points of practical importance left untouched. A section on the surgical anatomy of the teeth would be a useful addition. There is a good account of the recent work of L. Bolk on the development of the teeth, and his "dimeric theory" of the evolution of the tooth forms, which promises to engender as much discussion as the famous tritubercular theory, is adequately described. The two specimens of tooth formulæ quoted here do not correspond with those given by Bolk himself in the *Journal of Anatomy.*

So far as possible the original framework of the book as planned by Tomes is retained, but there are signs that it is becoming inadequate to the additions of new matter in successive editions; the book now reads somewhat jerkily and it is evident that the time for its drastic reconstruction is fast approaching. Yet, in spite of obvious defects in style and arrangement, it still remains indispensable to every student of the development and evolution of the teeth, and ranks as a contribution of first-rate importance to the literature of comparative anatomy.

A MANUAL OF PRACTICAL ANATOMY.

Part III.: The Head and Neck. By THOMAS WALMSLEY, Professor of Anatomy, Queen's University, Belfast. London: Longmans, Green and Co. 1922. Pp. 272. 10*s.* 6*d.*

THIS is the final volume of the excellent little dissecting manual, by Prof. T. Walmsley, the first two parts of which we have previously noticed. Part III. deserves as much commendation as its predecessors. We observe that Fig. 34 appears to favour the common though erroneous conception of the relation between the ninth nerve and the stylo-hyoid ligament; again, the relations between the nerve and the pharyngeal wall, as given some pages afterwards, are not too happily expressed. These are small blemishes, and we can congratulate the author on the production of a compact and useful practical guide to dissection.

GREEK BIOLOGY AND MEDICINE.

By HENRY OSBORN TAYLOR. London: G. G. Harrap and Co. 1923. Pp. 151. 5*s.*

THIS is an interesting little book forming one volume in a library which is appearing at the instance of a movement for acknowledging "Our Debt to Greece and Rome." This movement is American in origin, and most of its supporters, whose contributions make the issue of the volumes possible, reside in Philadelphia. Dr. Taylor has sketched in an easy simple style, but with real knowledge at the back, the influence of Greek biological and medical theories, and of classical medicine generally, upon modern therapeutics, thereby conforming to the design of the library as a whole, which is to show the vitality of the ancient thought, and the significance which it possesses in the development of intellectual life to-day. Dr. Taylor's summaries of the progress of medical science throughout the ages are just and well documented, and the little book serves excellently as an introduction to the fascinating study of the history of our art and science.

Reports and Analytical Records.

PITIBULIN.

(ALLEN AND HANBURYS, BETHNAL GREEN, LONDON, E.)

Post-pituitary solution prepared under the name of Pitibulin is derived from specially selected material and in the circumstances indicated may be relied upon as possessing high physiological activity. The use of pituitary extract in obstetrical practice, as well as its physiological action in collapse and shock, are well known, while contra-indications in certain stages of conditions of labour have also been much impressed upon the medical profession. Pitibulin is supplied in "Azoule" form ♏7½ (½ c.cm.), 6*s.* 6*d.*; and ♏15 (1 c.cm.), 12*s.* 6*d.* per dozen "Azoules"; "Azoule" Pitibulin, ♏15, with adrenin, gr. 1/200, 14*s.* 6*d.* per dozen "Azoules"; and "Azoule" Pitibulin, ♏7½, with adrenin, gr. 1/400, 10*s.* 6*d.* per dozen "Azoules."

NATURAL SALTS: BIOZONE BRAND.

(THE BIOZONE SYNDICATE, 28, BISHOPSGATE, LONDON, E.C.)

This preparation when analysed had the composition:—

Sodium bicarbonate	36·2 per cent.
Tartaric acid	26·2 ,, ,,
Sodium chloride	37·1 ,, ,,

On addition of water the granular mixture effervesces freely. Since the bicarbonate is slightly in excess of that required to neutralise the tartaric acid the resulting solution is alkaline. In the ordinary seidlitz powder Rochelle salt is a major constituent, but this is absent in Biozone salts and its place is taken by sodium chloride.

EDME MALT EXTRACT WITH COD-LIVER OIL.

(AGENTS: F. NEWBERY AND SONS, LTD., 27, CHARTERHOUSE-SQUARE, LONDON, E.C.)

The system of administering cod-liver oil in conjunction with malt extract has many advantages, among them being the avoidance of nausea experienced by people who cannot tolerate the undiluted oil. Messrs. Edme's product on analysis shows the following composition:—

Cod-liver oil	8·1 per cent.
Ash (mineral matter)*	1·38 ,, ,,
Proteins	5·74 ,, ,,
Water	14·10 ,, ,,
Malt carbohydrates, comprising maltose, dextrose, and dextrin ..	70·7 ,, ,,

* Containing phosphoric acid (P_2O_5) 0·6 per cent.

Active amylase is present in quantity, and the sample was entirely free from starch and salicylic acid. The total calorie value per pound of the mixture is 1762.

Cod-liver oil, as is well known, is one of the most valuable sources of vitamin A, while malt extract prepared, as in the present case, by mashing and concentrating at a low temperature, contains in addition the water-soluble vitamin B.

FREMLIN'S ENGLISH LIGHT BITTER ALE.

(MESSRS. FREMLIN, THE BREWERY, MAIDSTONE.)

When analysed this beer gave the following results:—

Specific gravity of wort before fermentation	1048·81°
Present specific gravity	1002·78°
Alcohol per cent. by volume	5·93
Extractives (total soluble matter, excepting ash, per cent.)	2·59
Mineral matter (per cent.)	0.25
Maltose (per cent.)	0·5
Dextrin (per cent.)	0·6

On removing the alcohol and fermenting with some additional yeast, 0·07 per cent. of free maltose disappeared, thus indicating that the beer was fully fermented and contained a mere trace of free sugar.

For a beer of this original gravity, the alcohol content is unusually high, thus ensuring palate fullness and keeping qualities. People of gouty or arthritic temperament who are forbidden malt liquors will find this bitter ale as free from objection as any we have encountered. The ale is attractive in appearance and palate, well gassed, and pours out bright to the last drop. No preservatives were detected. We examined this beer some years ago (THE LANCET, 1912, i., 1282), and our present analysis shows it to be almost identical in composition.

NASAL CREAMS.

(DUNCAN, FLOCKHART AND CO., EDINBURGH AND LONDON.)

Every medical man knows how often the right application to the nostrils brings remarkable relief to sufferers from various forms of irritation, and knows also that applications ordered without particular attention to their suitability may give no result, or lead to the aggravation of the uncomfortable conditions. Messrs. Duncan and Flockhart supply different forms of creams for nasal medication standardised according to whether the application is desired to be sedative (novocain), stimulating (oils of pine and eucalyptus, thymol, and menthol), astringent (zinc, tannic acid), antiseptic (carbolic and salicylic acids), or alkaline (bicarbonate of sodium). They supply also an iodised cream which contains 1 per cent. of free iodine in combination with pure carbolic acid. We can appreciate that many practitioners will like to know of these creams.

MANGANESE BUTYRATE AMPOULES.

(THE BRITISH DRUG HOUSES, LTD., GRAHAM-STREET, LONDON, N.)

This preparation, which is supplied in ampoules, is designed for the treatment of boils and carbuncles, whitlows, and other septic conditions, the first recommendation for the administration being that no incisions should be made into the lesion until two injections of manganese butyrate have been prescribed. The injection in some cases will abort the condition. Other indications for the use of the ampoules include erysipelas and gonococcal epididymitis, the injections in the latter case to be followed by contramine. The ampoules contain 1·5 c.cm. of a 1 per cent. solution, and are supplied in boxes of two ampoules at 1*s.* 6*d.* or six ampoules at 4*s.*

HUMAGSOLAN.

(HUMAGSOLAN, LTD., FARADAY HOUSE, 10, CHARING CROSS-ROAD, W.C.)

The remedy is the outcome of some experiments made by Prof. N. Zuntz, of Berlin, confirmed by A. Loewy (vide THE LANCET, Dec. 18th, 1920); they have been described by Prof. Dr. Carl Oppenheimer, of München in the Deutsche Allgemeine Friseurzeitung, 1920. A trial on a long-standing case of alopecia, the details of which are known to us, would seem to substantiate the claims for Humagsolan as a stimulator to the growth of the hair, but time, as far as this case is concerned, and further trial will be necessary before any more positive statement can be made. The preparation is put up in the form of metal-coated tablets, a month's supply of which is sold at the price of 12*s.* 6*d.*

LECTONA.

(LECITHIN, LTD., RICKMANSWORTH-ROAD, WATFORD.)

This is a tonic food prepared from fresh milk and malt extract combined with lecithin and vitamins, the preparation being designed to secure absorption of lecithin in an assimilable form without decomposition after administration by the mouth. The food obviously deserves trial, having been found of real value by many practitioners in cases of malnutrition and in various neuroses.

DRAYTON MILL TOILET PAPER.

(DRAYTON PAPER WORKS, LTD., SOUTH PARK, FULHAM, S.W.)

This toilet paper has been prepared with particular pains to ensure an even, soft, non-irritating material. It is supplied in rolls, "Iva," and in flat packets, "medicated manilla," and is already in employment in one of the large metropolitan hospitals, from which institution a valuable testimonial has been received.

THE LANCET.

LONDON: SATURDAY, MARCH 31, 1923.

RESTRICTIONS IN PRESCRIBING DANGEROUS DRUGS.

THE justifiable resentment of the medical profession continues to manifest itself towards certain aspects of the legislation as to dangerous drugs. There are two points in particular wherein the Home Office, however well-meaning, has been ill-advised. The first is the attempt in the Dangerous Drugs and Poisons Amendment Bill to draw a distinction between registered medical practitioners who are or are not in what is called "actual medical practice." This attempt, we are convinced, is mistaken and impracticable, and we are glad to learn that at the eleventh hour the Home Secretary admitted his error and withdrew the offending words. We need not dwell upon the terms of the Medical Act of 1858 which recognises only the description "legally qualified" or "duly qualified" medical practitioner. We need not recall the long years of special study and the stringent qualifying examination. It is enough to observe that the distinction which the words "in actual practice" seek to draw is wrong in principle and will be valueless in application. It has been decided judicially, we believe, that for the purpose of exemption from liability to jury service a barrister is "in actual practice" if, though he has never had a brief, he would consider the offer of one. We have heard of cases in which the authorities have sought to summon for jury service barristers who have either retired or have found non-legal employment. The barrister's answer in such a case is "My name is in the Law List; if you will send me a brief or ask me for an opinion I will show you whether I have retired or not." That answer has always proved conclusive. A barrister writing an opinion is in actual practice of his professional skill and training, no matter if he has been called to the Bar a dozen years and if this is the first opinion he has ever written. Similarly, a registered medical practitioner is in actual practice if he writes a prescription. Policemen and judges cannot say that he is not in actual practice until they can show that he has refused to prescribe. Is a medical practitioner who engages solely in research work not in actual practice of the special knowledge and professional principles in which he has been trained? If a qualified medical man is called upon to save life or alleviate pain, is he to answer that he has retired or is on holiday and therefore not in actual practice within the meaning of the Act? Or must he, before he prescribes, first swear an affidavit, in the nature of an income-tax return, setting forth his three years average of patients treated? The obnoxious words in the new Bill were to apply equally to registered dentists and registered veterinary surgeons, but we do not know how far the withdrawal here affects the position.

We pass to the second point—namely, the clause in the Dangerous Drugs Regulations of last October which forbids prescriptions to be given "for the use of the prescriber himself." On mere grounds of legality this provision is open to grave objection for the following reason. In delegating to departments the power to make restrictions of civic liberty Parliament has set up certain supposed safeguards against the abuse of that power. It has laid down certain conditions which the department must first comply with. We suggest that these conditions should be regarded as something more than a mere formality. Section 11 of the Dangerous Drugs Act of 1920 states that "every regulation made under this Act shall be laid before each House of Parliament forthwith," provision being added that either House may within 21 days thereafter present an address to His Majesty against an objectionable regulation, whereupon the offending clauses may be annulled by Order in Council. The precautionary requirement that the regulations must be laid before Parliament automatically attracts an additional precaution in an older statute. Under the Rules Publication Act of 1893 the Home Secretary, at least 40 days before he makes such regulations, must publish in the *London Gazette* a notice of his intentions, and during those days any public body can make representations and suggestions which "shall be taken into consideration" before the regulations are finally made. The Home Secretary duly announced his intention to make regulations by notice in the *London Gazette* of August 4th of last year. From that date the prescribed 40 days began to run. How far he took into consideration the representations and suggestions of public bodies we do not now inquire, since, as critics of the Rules Publication Act have pointed out, this supposed safeguard of public liberty is somewhat illusory. Government departments are in the happy position that they can either publish for criticism an objectionable clause and pay no heed whatever to the criticism, or they can publish a perfectly innocuous set of proposed regulations for criticism and then spring a complete surprise on the public by inserting an objectionable clause in the regulations when finally made. Up to this point, however, we will assume that the Home Secretary's action was unexceptionable, but his proposed regulations had no validity on August 4th of last year. They were merely a draft published for criticism for a period of 40 days, which expired during September. His next step was to make his final regulations. This he did on Oct. 2nd, 1922. It then became his duty to lay the result before Parliament *forthwith*. Parliament met on Nov. 20th, 1922. It met again on Feb. 13th, 1923. The House of Lords issue an official List of Rules and Orders presented during the session required by statute to lie for an appointed number of days on the table of the House. From this list we learn that these Dangerous Drugs Regulations of Oct. 2nd, 1922, were laid for a period which did not begin till March, 1923. Truly there is much virtue in "forthwith."

So much for the Parliamentary safeguards of the liberty of the subject. Whether a court of justice would hold that these regulations were rendered void by irregularity we do not presume to say, but pass to another aspect of the case. The clause that "the prescription shall not be given for the use of the prescriber himself" offends a principle of legislation more vital than any mere formality. It is futile to prevent a medical man from prescribing for himself if he cannot be prevented from having a stock of drugs in his consulting-room. When laws are futile, a court will not punish the citizen who breaks them. During the debate of Feb. 28th Sir SYDNEY RUSSELL-WELLS cited the case of a certain "very distinguished physician," who, while staying in a remote part of the country, was seized with violent abdominal pains. He wrote out a perfectly proper prescription and presented it to the village chemist. The latter declined to supply it unless on the prescription of another doctor.

The village doctor was some distance away attending a confinement. A brilliant idea struck the very distinguished physician. He wrote his wife's name on the prescription, obtained the medicine, went back to his hotel and drank it himself. In the eyes of the Home Office, we suppose, his manœuvre was a deliberate crime. But would any magistrate or judge inflict other than a nominal penalty in such a case? Laws which lead to such patently ridiculous situations had better not be made. We would add that when such laws involve penal consequences, it is more in keeping with our traditional notions of government that they should be made by Parliament itself and not by departmental ukase. The common sense of this matter can be stated in a very few words. No one is more familiar with the sinister results of the abuse of drugs than the medical practitioner. No one is more anxious to see the opportunities for that abuse drastically restricted. But neither in this nor in any other field of social effort will anything be achieved unless those who govern us are prepared to trust the medical profession.

◆

THE IODINE PROPHYLAXIS OF GOITRE.

Since the war Switzerland has been attacking with good will the domestic problem of goitre. Its prevalence is obvious even to the casual visitor in almost all cantons, but especially in those of Aarau, Berne, Fribourg, and Valais. Arising early in life, the affection tends to be regarded lightly by the population which does not feel its inconvenience as a rule until the later decades; but the turning-point in the campaign has been the very serious deterioration of national physique in the offspring of goitrous persons, brought home by the act of mobilisation. Some 1900 Swiss recruits are discarded each year on account of lowly stature due in large part to cretinoid change, and Prof. A. Oswald, of Zurich, has recently estimated at 50,000 the number of cretins recognisable at sight. Cretinoid idiots and deaf-mutes fill the asylums; 600–700 cretins are under institutional care in the canton of Berne alone, being 1 in 1000 of the inhabitants. And short of the need for segregation, there must be many degrees of thyroid insufficiency with more or less apathy and mental hebetude. Some there are who contend that it was this that kept Switzerland out of the war. The Swiss Commission on goitre which sat last June gave up its time largely to prophylaxis, and while some still maintained the infective origin of goitre and saw in the boiling of drinking water the means of prevention, Chatin's hypothesis, enunciated in 1850, held the field—that simple goitre is correlated with a low iodine content of drinking water.

Even before the year 1819 when Coindet, of Geneva, recommended iodine as a cure for goitre, it was common to see goitrous persons wearing necklaces of coral, amber, or seaweed, in the belief that goitre was affected by iodine content. Th. Kocher put up the question long ago to the chemists whether the thyroid did not contain iodine and refused to modify his conviction on obtaining at first a negative answer; it was only in 1895 that E. Baumann, of Freiburg, devised his method for demonstrating the minute quantities present. Baumann's discovery enabled him to conduct a painstaking research into the iodine content of the human thyroid in regions affected by goitre and free from it, with the result shown in the table. From this and other similar observations he concluded that the thyroid seeks by increase in size and surface to make up for the lack of iodine in neighbourhoods where the supply is scanty.

Number of glands examined	Place.	Mean weight of the glands in grammes.	Iodine content in milligrammes—	
			Of the whole gland.	Per gramme of dried gland.
30	Hamburg— Free from goitre	4·6	3·8	0·8
26	Freiburg— Average glands	8·2	2·5	0·33
12	Goitres	41·0	2·6	0·09

Hunziker described goitre in so many words as an adaptation to iodine-deficient nutrition. Dr. H. Eggenberger,[1] of Herisau, has recently set out the evidence regarding the diminution in iodine available for human consumption as the traveller proceeds from the sea-coast to the upland interior. In the neighbourhood of the sea the air and drinking water contain three times as much iodine as in Paris and ten times as much as in Switzerland, and Chatin himself demonstrated how poor in iodine is the water of alpine valleys. Water is not the only source of iodine in the bodily economy—eggs, milk, and uncooked green vegetables provide a portion; but in the last resort all these derive their supply of iodine from the soil of the country. The same has been found true on the continent of America. A recent study from the Laboratory of Physiological Chemistry in the University of Minnesota[2] contains a map showing the inverse ratio between the amount of iodine in surface waters or waters of shallow wells and the distribution of goitre, the data being taken from the files of the defectives who were found among drafted men available in the war department. Sea spray is responsible for carrying iodine for many hundreds of miles from the sea-coast and from the Great Salt Lake.

Heretofore iodine has been given for goitre in doses vastly in excess of those required for prevention. The treatment, in fact, has itself been a danger. Hyperthyroidism is distinctly rare in Switzerland, but at least one-half of the cases of Graves's disease which do occur are attributed to excessive medical prescription of iodine. The amount of iodine required in the daily economy of the thyroid is, in fact, exceedingly small. Hunziker suggests that whereas goitrous patients formerly received as much as 1 g. daily of potassium iodide for weeks, in point of fact a 10,000th part of this daily dose, or 0·1 mg., had an anti-goitrous action, and, used in this way, 1 g. of potassium iodide would last 10,000 days or 27 years, and 3 g. suffice for a life-time. In a patient taking 5–6 drops daily of Coindet's tincture free iodine can be demonstrated in the urine and the same has been shown for children after using the well-known chocolate iodo-starin tablets. The quantity needed being so small and the time over which it should be taken so long, the natural course is to incorporate iodine in some common article of diet. Table salt is the obvious carrier. Its advantages as a medium lie in the facts that all civilised persons daily take a certain definite quantity of NaCl varying from 5–20 g., that over-dosage is impossible, and that while table salt is not dear it possesses a certain market value and is therefore not likely to be wasted. Chlorides and iodides occur together in nature and agree well. After an intensive campaign of education by the Red Cross the canton of Appenzell decided last

[2] Simple Goitre as a Result of Iodine Deficiency. J. F. McClendon and Agnes Williams. Jour. Amer. Med. Assoc., March 3rd, 1923.

February to introduce the general use of so-called *Vollsalz*, containing an addition of 0·25 to 0·5 g. KI to every 100 kilos. With an average individual consumption of 10 g. a day this gives a daily dose of 0·025 to 0·05 mg. KI. The cost of prophylaxis on this scale would not exceed 1 centime a year for each inhabitant and the cost for the whole of Switzerland not more than 40,000 francs. Should this simple measure succeed, not only in hindering the development of goitre with its 2000 palliative operations each year, but also the cretinoid degenerations of all kinds in the offspring, its value can hardly be exaggerated.

CARRIERS IN INFECTIOUS DISEASES.[1]

Knowledge and experience concerning carriers in relation to infectious diseases have advanced rapidly in the years since 1903, when prominence was given to the subject by Koch. A recent treatise by Nichols and Kelser[1] deals with over 26 bacterial diseases in which carriers are important. At least ten of these affect man alone, four concern the lower animals, and more than twelve others concern both man and the lower animals. Other diseases are mentioned in which carriers are probably of importance, but cannot be definitely recognised and traced for various reasons, largely because the infective agents are unknown or are filter-passers. The evidence has rapidly accumulated that in many, perhaps in most, infectious diseases the materies morbi is conserved and distributed to fresh victims more by the healthy or by quasi-healthy convalescents than by the sick. The difficulty in deciding which individual should be called a carrier and which a mild case of disease of long or short duration is a point at issue running through the literature of the subject. A carrier is defined by Nichols as "an individual who harbours and transmits pathogenic parasites without showing the usual evidences of infection." Little fault can be found with this definition, if it is allowed to include the mild and chronic forms of infection which, though distinctly pathological, do not show the commonly recognised acute symptoms associated with the disease. Such cases comprise inflammation of the gall-bladder and cholelithiasis due to persistent enteric infections, chronic rhinitis or tonsillitis associated with infection by the *Bacillus diphtheriæ*, infection of the udder of the goat with *M. melitensis*, and of the uterus of the cow with *B. abortus*. In these instances the persistence of the carriers is due to true chronic infections; these constitute the chief modern discovery which has accentuated the danger of carriers.

The pathology of chronic carriers deserves and receives considerable attention. Nichols and Kelser insist that the chronic carrier has usually, if not always, a localised infection, which implies a general immunity but an insufficient local immunity. Importance is rightly attached to the further search for methods which will be of use in curing the local infection. The nature of the case suggests that local measures are more likely to be effectual than general, since a general immunity already exists. The only hitherto successful means of treatment appear to be surgical, but X rays are suggested for certain cases. It is stated that excision of the gall-bladder cures 50 per cent. of biliary carriers, the condition being diagnosed by Einhorn's tube. Extirpation of the tonsils and treatment of nasal obstruction appear by all accounts to be successful in a large proportion of carriers of *B. diphtheriæ*. It should, however, be borne in mind that the carrier's general immunity may be low, especially in nasal carriers (membranous rhinitis), and either the Schick test should be performed and immunising measures adopted if necessary, or a precautionary dose of antitoxin given before the operation if the Schick test is for any reason impracticable. No countenance is given by Nichols and Kelser to the doctrine that *B. diphtheriæ* may be observed to become non-virulent during convalescence, but it is perhaps too hastily assumed that all "non-virulent carriers" are harmless and are in fact, according to the nomenclature used, "pseudo-carriers." This point does not seem to have been finally settled yet, and we deprecate the rough test of virulence of a *B. diphtheriæ* strain suggested by the manual. The results of such tests with impure cultures or without antitoxin controls are nearly always inconclusive, since diphtheria-like appearances may be produced by streptococci and a negative result may be due to other contaminations neutralising the toxin. The aspect from which the authors approach their subject is that of a public health officer and is eminently practical. Nichols insists (rather strongly, perhaps, to those of British habits of mind) that when the individual interest is in conflict with the welfare of the community the latter must always be allowed to prevail; but he recognises that the carriers (who may be numerous) also constitute a part of society and require consideration. He maintains that the carrier should be sought by the health officer or his specially trained ally, the "phorologist," who should be no narrow specialist, but a widely educated medical man with sufficient knowledge of clinical medicine, bacteriology, and epidemiology to follow the right line of search and form his own opinion on the evidence. It is necessary not only to find a carrier, assess his importance to the community, and prevent his doing harm, but also to localise the seat of his infection and, if possible, to cure it. The study of carriers in veterinary diseases is no less appropriate and fruitful than in human medicine, even apart from the numerous instances of interdependence of disease in man and other animals. The case of white diarrhœa in chickens is a remarkable one. The recovered chicks become carriers and, if hens, may carry the causal agent, *B. pullorum*, in their ovaries for life. The eggs are then infected and many become sterile; others hatch, and the resulting young brood are infected, and after spreading infection around them by their fæcal discharges either die or, living, perpetuate the disease as carriers. The blood serum of the infected birds gives evidence by an agglutination test of the carrier state and enables a campaign of eradication to be undertaken.

A defence of the study and importance of carriers is unnecessary at this date; indeed, more accurate information concerning their numbers and distribution in many diseases is still urgently needed, since their essential relation to the spread of disease is undoubted. This does not, however, imply that it is always necessary to discover and isolate carriers in order to check an epidemic or to prevent the occurrence of fresh cases of illness. It would be a serious error to attempt to investigate and deal with all carriers on the same lines. An intensive campaign for the detection and isolation of carriers of streptococci or *B. fusiformis* would be absurd in our present state of knowledge. Nevertheless, the search for carriers wherever practicable is worth while, if only to complete our knowledge of the natural history of disease. The correlation of the results of the Schick test and carrier work in diphtheria is already holding out much hope and giving encouragement for great gains in the near future. The study of the serological types of the *B. diphtheriæ* isolated from carriers and new cases is suggesting lines of advance, giving hints as to future means of tracing the topographical course of outbreaks, and perhaps even correlating the severity of the disease with special types of bacillus. During 1920–22 the average number of cases of diphtheria in London per annum increased to 15,128 from 8880 in 1911–20, and at the same time the carrier rate in schools rose from 7·5 to 10 per cent. Direct evidence of the danger of carriers was not wanting. Dr. Graham Forbes, in a recent communication to the Medical Officers of Schools Association, stated that he had found reason to associate this epidemic in London schools with the type III. bacillus. The curious observation that carriers of virulent *B. diphtheriæ* may, during non-epidemic times, attend school without either the spread of the bacillus to others or the occurrence of cases, is probably explained by the presence of a high proportion of immune scholars or by the relatively scanty distribution of bacilli which some carriers effect. The difference in the relative efficiency with which different carriers disperse the infection which they carry to their neighbours has often been noticed in the case of the enteric as well as in that of the diphtheria carrier. It is to be hoped that increased application of the Schick test in this country will throw light on the varying immunity of the population, and enable active immunisation to be carried out where required. The results of tests so far published by Copeman, O'Brien, Eagleton, and Glenny have given results comparable with those obtained in the U.S.A. and elsewhere. Correlation of the results with those of carrier examination has led and will further lead to important advances in theory and practice. There has never hitherto been sufficient accurate laboratory work available to meet the demands of the progressive health officer.

Nichols, M.D., Major, Medical Corps, U.S. Army; Instructor in Bacteriology, Parasitology, and Preventive Medicine, Army Medical School, Washington, D.C. With a Section on Veterinary Medicine by R. A. Kelser, D.V.M., Captain, Veterinary Corps, U.S. Army. Baltimore: Williams and Wilkins Company. 1922. Pp. 184. $3.50.

Annotations.

"Ne quid nimis."

ECLAMPSIA.

Innumerable medical and operative procedures for eclampsia have been adopted and abandoned. Bozzi's dilator was practically invented for the treatment of eclampsia and is now generally found in the hospital museum; Cæsarean section, after an extensive trial, is generally condemned. Numerous drugs have also been tried, but the mortality has remained unaltered, between 20 and 25 per cent., irrespective of the variety or combination of treatment adopted, with the exception of two lines of treatment which have been followed during the past 20 years, more or less unchanged, and give a mortality result of about 10 per cent. These two treatments were instituted by Stroganoff and Hastings Tweedy respectively; the former has been carried out extensively on the continent and in America, while the latter has chiefly been adopted in Ireland. Both have suffered from incomplete acceptance and prosecution. On p. 666 of our present issue Dr. Gibbon FitzGibbon sets forth in some detail the Hastings Tweedy treatment as it is carried out in the Rotunda Hospital, Dublin. In commending his article to the attention of practitioners we would recall the conference on eclampsia[1] held at Liverpool in June, 1922, where the Rotunda method of preventing and treating this disease was acknowledged by several authorities to give good results compared with other methods, even though the theory on which it is based was not universally accepted. At the last annual meeting of the British Medical Association the matter was again discussed in the Section of Obstetrics and Gynæcology[2] and the case for the expectant and eliminative treatment still further established.

MENTAL HOSPITALS IN NEW SOUTH WALES.

The Inspector-General of Mental Hospitals for New South Wales in his report for 1922 complains, apparently not for the first time, that the ten existing institutions are overcrowded. The lack of accommodation is particularly acute in the case of criminal lunatics, some of whom have at present to remain in the gaols. Otherwise the working of the mental hospitals is regarded as satisfactory, and the recovery rate of 43 per cent. is a high one. It is interesting to note that a Bill has been introduced to amend the Lunacy Act, by classifying patients into three groups, according to the degree of restraint they require. In the first group are those amenable to voluntary treatment in special wards of a general hospital; in the second "those who will be subject to detention where the exercise of same is in the patient's interest," these patients to be treated in special hospitals—the patient being admitted as a voluntary boarder and certified only if necessary subsequently; in the third group are those "who require compulsory detention either for their own protection or that of the public." There exists already a psychiatric clinic under the direction of Sir John MacPherson, where out- and in-patient treatment is available on a voluntary basis; there is also a voluntary home for inebriates, but no provision for the care of any but the certified is made as yet by the law of the State.

HOUSING IN SCOTLAND.

The instalments of the Scottish Census have appeared in steady succession, and we have before us the twenty-eighth part of Vol. I., giving the statistics compiled from Census returns for the county of Perth. Vol. I. will be completed when the thirty-seventh part is issued. Each of these parts includes full particulars respecting the different parishes, burghs, and other administrative areas in each county, and a detailed statement as to age-distribution, orphanhood, and conjugal condition, and as to occupations, industries, birth-places, housing, and institutions within the county. From a comparative examination of the housing statistics of eight important counties in Scotland, it is now possible to derive a general impression of housing conditions in the northern country in the Census year. The general results are shown in Table I.

Table I.

Counties.	Percentage of houses (r. = rooms) containing—					Percentage of population living in houses with—				
	1 r.	2 r.	3 r.	4 r.	5 r. or more.	1 r.	2 r.	3 r.	4 r.	5 r. or more.
(1)	19·0	48·3	17·8	6·1	5·1	14·2	49·8	18·2	6·0	4·8
(2)	13·2	42·1	18·2	9·1	9·4	9·3	41·5	18·6	9·4	9·8
(3)	11·1	47·6	19·8	6·9	7·0	7·7	47·4	20·3	6·8	6·6
(4)	8·2	36·1	23·1	13·1	9·6	4·8	34·3	23·1	13·1	9·3
(5)	6·1	42·6	24·9	11·6	8·1	3·6	40·5	25·8	11·6	7·9
(6)	5·1	20·8	26·0	14·8	20·3	2·1	15·9	25·4	14·9	21·7
(7)	5·0	24·9	24·3	14·5	16·4	2·1	20·2	23·5	14·4	17·1
(8)	4·1	28·8	28·7	11·5	15·5	2·1	24·0	29·9	11·7	16·5

Counties.—(1) Lanark. (2) Ayr. (3) Dumbarton. (4) Midlothian. (5) Fife. (6) Inverness. (7) Perth. (8) Kincardine.

The proportion of dwellings comprising only one room varied from 4·1 per cent. in Kincardine to 19·0 per cent. in Lanark (including Glasgow). The counties of Ayr, Dumbarton, and Midlothian (including Edinburgh) came nearest to Glasgow and greater Glasgow in respect of the high proportion of one-roomed dwellings, while in Fife, Inverness, and Perth housing conditions were less unfavourable. Of course, some dwellings are occupied by single persons and some by married couples without children; but a dwelling comprising less than three "windowed rooms" cannot be regarded as satisfactory; and it is significant that housing in Lanark, Ayr, and Dumbarton stands condemned in this respect for more than half the total dwellings in these counties. The classification of houses by number of rooms can be checked by the statement in the latter half of the preceding table, which shows the proportion of the total population which at the time of the Census was living in houses of different sizes. In Lanark 14·2 per cent. of the total population dwelt in single rooms, and 64 per cent. in one or in two rooms. In Ayr 50·8 per cent. of the total population lived in one or in two rooms, the proportion in other counties thus unsatisfactorily housed being as shown in the table. The conditions thus indicated are deplorable. It may be urged, however, that it is small families especially which live in these one- and two-roomed dwellings. The second half of Table I. goes far to disprove this explanation; and the real facts are shown, in part, in Table II., which has been extracted from other parts of these Scottish reports.

---

[1] See The Lancet, 1922, ii., 89 and 144.
[2] Ibid., 1922, ii., 713.

TABLE II.—*Percentage of the Population per Room.*

—	More than 4 persons to a room.	Not more than 2 persons to a room.
Lanark	15·2	42·4
Ayr	12·1	50·4
Dumbarton	10·6	49·1
Fife	6·4	58·2
Midlothian	4·4	65·8
Kincardine	1·5	73·4
Inverness	1·4	79·6
Perth	1·2	80·6

All rooms having windows are reckoned as dwelling rooms, and not only living and bedrooms, but also kitchens and sculleries are included in the accommodation as shown in the above table. Including such rooms, nearly 81 per cent. of the dwellings in Perth did not average more than two persons to a room, in Lanark the corresponding proportion was 42·4. In Lanark 15·2 per cent. of the total dwellings had living in them more than four persons to a room (defined as above); in Ayr 12·1 per cent., and in Dumbarton 10·6 per cent. were thus overcrowded.

The figures speak for themselves. The desire for good housing in a large part of Scotland is lamentably low, or there is lamentably deficient housing accommodation, or both these causes of insanitary overcrowding are operating to an extent which is nationally discreditable. Nor can there be doubt as to the mischief arising from family life in one, in two, or even in three rooms. The startling figures published by the late Dr. Burn Russell as to one-roomed dwellings in Glasgow are well known. They have been supplemented by more recent and carefully corrected statistics prepared by Dr. A. K. Chalmers, which show the excess of acute infectious diseases, of tuberculosis, and of nutritional diseases, and of infant mortality in the smaller dwellings; and Sir Leslie Mackenzie contributed to the Scottish Housing Commission's report an eloquent indictment of the results of bad housing in Scotland. To argue that bad housing is chiefly an index of the low standard of physique of intelligence and morality of those thus housed is a *petitio principii*; and no social well-wisher can be satisfied until the public conscience has been aroused to supply the deficiencies of housing accommodation and to educate all wage-earners to a standard of life which will not be contented to accept less than is necessary for health and morality.

HÆMATEMESIS IN NEPHRITIS.

ACCORDING to Dr. Howard F. Shattock[1] of the Postgraduate Hospital, New York, who records an illustrative case, hæmatemesis is an unusual complication of chronic nephritis, and when it does occur is rarely profuse. Richard Bright himself, in 1829, spoke of gastric and intestinal hæmorrhage in some cases of nephritis, but he regarded the occurrence merely as a coincidence without any ætiological relationship between the two conditions. Even before Bright, Latour, in 1815, described epistaxis and other forms of bleeding in dropsy, and earlier still Morgagni reported the case of a woman with the odour of urine in her breath, who vomited blood, and had epistaxis with favourable results. Later the association of various forms of hæmorrhage, including gastro-intestinal hæmorrhages in nephritis and uræmia, were noted by a number of observers, including George Johnson and Moxon in this country, and Fournier, Lancereaux, Mathieu and Roux in France, most of whom described the intestinal hæmorrhages which were more frequent than the gastric. Riesman regards renal disease as the cause of the hæmorrhagic diathesis, the factors being hypertension, arterial disease, and toxæmia. No uniform pathological findings have been reported in these cases, so that no conclusions can be drawn as to the causes or pathology of hæmatemesis in nephritis. In Dr. Shattock's case, which occurred in a woman aged 31, hæmatemesis of a "cupful" of blood was not preceded by any abdominal pain or other symptoms referable to the gastro-intestinal tract except anorexia, nausea, and vomiting during the last three months. Slight hæmatemesis recurred on three occasions during the first 24 hours after the first but not subsequently. The urine had a specific gravity of 1010–1016, a persistent faint trace of albumin and a few casts. The blood-urea was low; 11·4 mg. per 100 c.cm. of blood and the uric acid was increased; 3·5 mg. in 100 c.cm. of blood. The blood pressure was 194 systolic, 124 diastolic. Temporary improvement took place under treatment, but death from uræmia occurred seven months after the hæmatemesis. Autopsy was refused.

GOVERNMENT GRANTS TO VOLUNTARY HOSPITALS.

THE Voluntary Hospitals Commission have now dealt with all the applications for grants in respect of 1921, except for a limited number of areas in Scotland in which Local Voluntary Hospital Committees were late in being established. The total deficits reported to the Commission amounted to £295,170 for London, £425,727 for the rest of England and Wales, and £15,340 for Scotland. The total deficits reported for the whole of Great Britain amounted to £736,237, as compared with the estimate of £1,000,000 by Lord Cave's Committee on which the Government grant of £500,000 was based. Grants totalling £424,983 have now been made on the basis of pound for pound of new money raised or in sight, except in a limited number of cases in which emergency grants have been made to hospitals, which had exhausted their realisable assets and without assistance from the Commission would have been compelled to close beds. The grants are as follows: London, £225,000; England and Wales[1] (excluding London), £194,242; Scotland, £5741. The London hospitals have received their full share of the grant, but a balance of £75,017 still remains for distribution in the rest of England, Wales, and Scotland. This balance has been apportioned on the basis of Lord Cave's estimate as follows: England and Wales, £45,758; Scotland, £29,259. The Local Voluntary Hospital Committees in England and Wales and the Consultative Committee in Scotland are being asked to formulate proposals, subject to the Treasury conditions, for the distribution of these balances towards the liquidation of the deficits which accumulated prior to 1921.

CONJUGAL INFECTION IN TUBERCULOSIS.

Dr. Paul Roussel, assistant physician to the Sanatorium des Pins and the Villemin Dispensary at Nancy has made a valuable contribution[2] to our knowledge of a much debated subject. At the dispensary he found that husband and wife were both tuberculous in 11·6 per cent. of 423 families investigated, and with 25 per cent. of tubercle among the children. The figures led him to conclude on further scrutiny that in 11·6 per cent. of *open* pulmonary tuberculosis conjugal infection had occurred, and 37·5 per cent. of the children were infected; if *all* cases were included the cases of conjugal infection dropped to 5·2 per cent. and the infection-rate of the children to 25 per cent. It is noted that conjugal infection is in general milder than other infections, especially those of children, the difference being explained by a "surinfection" in one case and a "primoinfection" in the other; that is by the results of allergy. Dr. Roussel finds the phenomena of allergy to vary with the dose of toxin, the number of doses, and the interval between each. This also explains why the children of tuberculous parents often pick up so remarkably when removed even temporarily from further infection. An infection frequently repeated at short intervals seems the most dangerous, and it is the type of primary infection which determines the widely diverging conditions met with in those who have a family history of tuberculosis rather than different forms of heredity.

[1] Includes a grant of £3950, which has not yet been paid.

[2] La Tuberculose Conjugale: Contagion et Mariage. Paris: A. Maloine et Fils. 1922. Pp. 140.

Dr. Roussel has no doubt that the marriage of persons with open, or progressive, tuberculosis should be forbidden, but in the case of healed tuberculosis there is room for discussion, which must be preceded, however, by an understanding of what is meant by healed tuberculosis. If a few years have elapsed without symptoms, marriage may be allowed. It seems as if the influence of the medical man in preventing the marriage of tuberculous subjects is greater in France than in this country. The author recognises the great difficulties of isolating tuberculous husbands or wives in the home; some of the difficulties encountered by health visitors at Nancy are narrated and practical suggestions are made. A separate room is of the first importance and, if unattainable, a space of at least 5 feet should intervene between the beds. Special precautions are recommended during pregnancy. Much importance is attached to nocturnal isolation, family contact during the day being rightly considered of far less moment. The author, however, seems to emphasise insufficiently the danger of the early morning cough. The Villemin Dispensary is happy in having at its disposal for loan to patients a supply of hygienic bedsteads and bedding, a step which has hardly been tried in this country. Dr. Roussel concludes his study with two quotations which suggest to him an optimistic outlook: "However fertile a field, the only seeds to grow are those sown by the farmer, the birds, or the wind" (Calmette); "The forest of Fontainebleau is strewn with acorns which will never become oaks" (Vallin).

VENTILATION IN WEAVING SHEDS.

RECENT progress of knowledge in the science of ventilation has been bound up with various attempts to solve the problems of atmospheric conditions in humid weaving sheds. No great success attended the earlier efforts which were made. First, in reliance on the theory of chemical impurity, 600 cubic feet of fresh air per hour per person employed was called for; next a carbon dioxide standard (not to exceed 9 parts per 10,000) was fixed; at the same time permissible limits of humidity were determined. But, throughout, that most delicate of reagents, the human body, personified by the Lancashire operative, declined to be satisfied with the steps taken. The work of Haldane, L. Hill, and Boycott upon the effect of wet-bulb temperatures on body heat followed; then came physiological observations on weavers themselves by Pembrey and Collis; and lastly, the introduction of the kata-thermometer by use of which the long-time complaints of the weavers are being justified. All is set forth in an excellent preface to the latest report of the Industrial Fatigue Research Board.[1] The report itself, which contains statistical tables and graphic diagrams, is based upon data collected at hourly intervals during winter and summer with regard to the cooling power of air in weaving sheds; seven "humid" sheds—i.e., with installations for humidifying the air—and one "dry" shed were investigated. In the dry shed the cooling power and evaporative power of the air was higher than in the humid sheds. Generally speaking, in the humid sheds the wet-bulb temperature was found to rise through the day, and simultaneously atmospheric conditions became less satisfactory. The conclusion arrived at is that the operatives in these sheds are exposed to atmospheric conditions which are physiologically unsatisfactory, and the suggestion follows that the cooling power of the air should be sufficient to prevent visible sweating, a standard difficult to maintain when the temperature rises above 70° F. Nevertheless, shed temperatures and humidities are, within limits, under the control of the management. The air in humid sheds was found to compare unfavourably with that in other factories investigated, such as engineering, shoemaking, laundries, and potters' shops. The conclusion of the matter is that weavers require more air movement, and that devices are needed to bring this about without impairing the weaving quality of the cotton. There is here an antagonism between the human body and the cotton thread; what is good for the latter, is not beneficial to the former. A further report is promised dealing with variations in efficiency in weaving; but, as is pointed out in the preface, information is still lacking as to what effect, if any, the discomfort complained of by the weavers has upon their general health. We are glad to note, however, that this matter has not been lost sight of, and is to be investigated.

DEATH FOLLOWING NITROUS OXIDE ANÆSTHESIA.

AT a recent meeting of the Société de Thérapeutique, of Paris, Dr. Étienne Chabrol[1] reported the case of a woman, aged 50, who developed symptoms of apoplexy a few hours after an operation for epithelioma of the breast, under nitrous oxide anæsthesia. The operation, which was carried out by M. Labey at 9 A.M., consisted in amputation of the left breast and clearing out the axilla. Owing to the abundance of metastases the patient was kept under the anæsthetic for an hour and a quarter. About three hours after termination of the operation she came round from the anæsthetic, but almost immediately afterwards sank into a deep sleep. She was still asleep when seen by Dr. Chabrol at 5 P.M., but no facial deformity was noticed at that time, and the pulse was normal. At 8 o'clock on the following morning Dr. Chabrol was at once struck by the presence of left facial paralysis, which was accompanied by hypertonus of the lower limb and Babinski's sign on the same side. In spite of bleeding and the application of leeches over the right mastoid the signs of apoplexy rapidly became more pronounced and death took place at 5.30 P.M, exactly 32 hours after the anæsthetic. No mention is made of an autopsy. Apart from Paget's disease of the nipple, which had preceded the epithelioma of the breast for several years, the patient had always enjoyed good health. A week before the operation the heart, blood pressure, and urine were found to be normal, and the Wassermann reaction was negative. A few hours after the anæsthetic 100 c.cm. of urine were obtained and showed a trace of albumin. Examination of the blood a few hours before death showed 1·15 g. of urea per litre. In his comments on the case Dr. Chabrol remarked that Chevassu and Rathery, at the Congress of Urology, held at Strasbourg in October, 1921, had emphasised the danger of nitrous oxide anæsthesia in patients with hypertension. The present case showed that in the administration of this anæsthetic the probable duration of the operation and the age of the patient should be taken into consideration. In operations of short duration laughing gas deserved the reputation which it enjoyed in dental surgery, but in operations likely to last an hour or more a case of this kind should serve as a warning. The patient's age was a more valuable guide than the best blood-pressure apparatus, as it indicated the possibility of localised vascular sclerosis, which, as the present case exemplified, was not always revealed by the peripheral blood pressure.

THE FUNCTIONS OF THE PARATHYROID GLANDS.

NOTWITHSTANDING the large amount of work done to determine the functions of these organs, our exact knowledge of their physiology is even now singularly limited; the observations of Harald A. Salvesen, of the Physiological Institute of the University of Christiania, are the more welcome.[1] Of the many theories as to their functions, only three have gained some importance—viz., that the parathyroids control (1) the guanidine metabolism, and so regulate the tonus of muscles; (2) the calcium metabolism, and (3) the acid-base equilibrium, their removal causing alkalosis. Like others of the ductless glands, they are supposed to control the sugar metabolism to some extent. Salvesen has studied more especially the changes in certain constituents of the blood that follow upon partial and complete parathyroidectomy in dogs, care being taken to leave enough thyroid tissue to prevent cachexia.

First, as regards partial thyroidectomy, three glands were removed; and in no case did the dogs operated on show any symptoms of tetany, and apart from a little depression and loss of appetite in the first few days, showed no symptoms at all. The blood-sugar was unchanged, the alkali reserve was usually lowered the first few days after the operation and corresponding to this lowered alkali reserve there was an increase of acid elimination; the serum calcium decreased from a normal value of 10 mg. to a minimum of 7 mg. per 100 c.cm. Within two weeks the calcium was restored again to the normal. By way of control, to a normal dog were given large doses of N/10 hydrochloric acid for three weeks; there was a heavy drop of alkali reserve, but the calcium was unchanged. The calcium decrease found in partial parathyroidectomised dogs cannot be due to acidosis, and it was also found that it was not due to the anæsthetics used.

Complete parathyroidectomy was performed in 10 dogs—in 4 all the parathyroids were removed at once, and in 6 three glands had been removed previously. All of these 10 dogs developed acute tetany; 5 of them died untreated within 3½ days. Four were preserved by treatment and passed into a state of latent tetany. During the development of the symptoms in acute tetany, the blood-sugar was unchanged, and there was no hypoglycæmia even during the most acute symptoms shortly before death. The alkali reserve almost invariably decreased after the operation; it might be normal even during tetany, and corresponding to this decrease there was an increase of the excretion of acids, but no evidence of alkalosis. Calcium dropped from the normal value of 10 mg. per 100 c.cm. serum and was, when tetany occurred, always below 7 mg., usually much lower. There seems to be in this acute stage a certain relation between the degree of lowering of the calcium and the violence of the symptoms. The inorganic phosphorus of the blood serum increased considerably.

Some observers have noted that in spite of the intravenous injection of calcium chloride, parathyroidectomised dogs die, and have come to the conclusion that the decrease in calcium found in tetany is not to be regarded as the essential cause of the symptoms. The author, however, finds that a total of 2 g. a day injected intravenously checked the symptoms, but that next day there was violent tetany, which could again be checked by an injection. It was also found that whenever convulsions reappeared after injection, the serum calcium fell to the same low level again, indicating that the injected calcium was disposed of in some manner. Experiment showed that there was excreted an amount of calcium corresponding to the amount injected, but more than nine-tenths was excreted in the fæces, and less than one-tenth in the urine. The rapid disappearance of calcium may explain why calcium treatment reported by previous observers fails to keep the animals alive.

Completely parathyroidectomised dogs, however, may be kept alive, and to all appearance normal, by proper feeding, though a condition of latent tetany may exist. Of four such dogs two recovered spontaneously during milk feeding, and the other two after vigorous calcium treatment—1 to 2 g. of calcium chloride a day intravenously—combined with milk feeding. After a week or two the calcium could be omitted without any symptoms, and the dogs were to all appearance normal on a milk diet. These four dogs could be kept alive indefinitely on this diet. They could, however, be brought into a state of tetany—usually within 24 hours—by changing the diet to meat. Such dogs—apparently normal—had one characteristic finding in the blood: the calcium was still low—usually between 5 and 6 mg. The inorganic phosphorus was usually at the upper border of the normal level or above. Dogs fed on milk diet—500 c.cm. a day, with bread and porridge—after the first critical period was passed, could be kept without symptoms for as long a time as wanted. Meat always produced tetany, loss of appetite, and depression. Experiment showed that it was the withdrawal of milk which produced tetany, not meat diet in itself, and the author concluded that milk contains substances which prevent tetany. This substance proved to be calcium, of which milk contains 1·2 g. per litre, corresponding to 10 g. of calcium lactate. Milk from which 90 per cent. of the calcium was precipitated is useless in preventing tetany. If, however, soluble calcium salt was given, the dogs kept normal on any diet. Now when meat was given in excess, the dogs increased in weight and were normal in all their actions. Analysis of serum calcium always showed that at the moment when the symptoms were relieved, there was an increase in the calcium content of the blood, showing that it is the actual absorption of calcium which cures the symptoms. The same increase in serum calcium was seen when milk checked the symptoms. The protein metabolism in dogs with latent tetany, on a milk diet and without symptoms, was normal. The non-protein nitrogen and blood-urea were normal both in the latent state and during tetany, and the blood-sugar was unchanged in both these states. The tolerance for glucose given orally was lowered, and the lowered tolerance is not due to increased permeability of the kidneys, but to a functional disturbance of the glycogen-forming organs. There would seem to be a relation between sugar tolerance and blood calcium in these animals. Guanidine injections in a normal dog in amounts large enough to produce violent convulsions did not alter the serum calcium, but produced hyperglycæmia and lowering of the alkali reserve; phosphates remained normal.

These experiments show that the characteristic feature in the chemistry of parathyroid insufficiency is the drop in blood calcium, which is more marked the more parathyroid tissue is removed. They suggest that the parathyroids control the calcium metabolism, and by doing so they influence the functions not only of the muscle and nerve tissue, but probably of all organs. When the parathyroids are removed, the threshold for the excretion of calcium in the intestines is lowered.

THE PATHOLOGY OF INFLUENZA.

AT a meeting of the Pathological Section of the Sheffield Medico-Chirurgical Society, held on March 22nd, Prof. J. G. Adami gave a survey of the development and pathology of the great influenza outbreak of 1918. It had been his task, he said, to draw up a general report on influenza affecting the troops. Although finished two years ago, unfortunately this report had not yet been published. The commencement of the epidemic was usually set down as April or May, 1918, but sporadic groups of cases, often called "purulent bronchitis," and apparently influenzal, had occurred as far back as December, 1916. He would, therefore, regard the epidemic as presenting three successive phases in its development: (1) From December, 1916, to May, 1918—sporadic groups of cases; (2) from May to August, 1918—great number of cases of short duration comparatively mild, the "three days' flu"; (3) the autumn months of 1918—a very great number of severe cases with an appalling mortality, chiefly from pneumonia. Prof. Adami enumerated certain things which helped the pathologist to explain the protean manifestations of the disease. One and the same organism might cause different lesions in different stages of the epidemic, owing to its having acquired a higher degree of virulence as the epidemic progressed. Secondary invasions were common. The sporadic cases of purulent bronchitis usually presented the following features: Acute bronchitis and bronchiolitis with pus in the lumen, denudation of the lining membrane, and the presence of a small Gram-negative cocco-bacillus; the air-cells were but little affected. The most striking changes were found in the smaller bronchi; in the later stage the smaller bronchioles were often found completely denuded of mucous membrane. In some of these cases Pfeiffer's bacillus was grown in pure culture from the secretion in the terminal bronchioles. The influenzal nature of the majority of these cases before 1918 was not recognised, but the pathological lesions were essentially similar to those found in the influenza cases of 1918. A cardinal feature in the 1918 cases was the regular presence of tracheitis. The larynx and uppermost rings of the trachea usually escaped; but the bifurcation and lower third of the trachea were almost constantly acutely inflamed. Here intense purple congestion was followed later by desquamation of the ciliated epithelium. This acute desquamative tracheitis and bronchitis apparently commenced near the bifurcation and spread both upwards and downwards. Prof. Adami regarded it as of great significance. Removal of the ciliated epithelium at this spot removed the last effective barrier to the invasion of the lungs by inhaled micro-organisms. This helped to explain the great frequency of secondary invasions in influenza. It was significant, further, that the secondary infections met with most commonly were from those organisms which were least susceptible to the bactericidal action of serum. Further, it should be remembered that it would be precisely on this area—the neighbourhood of the bifurcation of the trachea—that those micro-organisms which had succeeded in passing the defences of the upper air passages would be likely to impinge. The difference in the lesions found in the lungs in the last and most severe stage of the epidemic from those previously found in the earlier and less severe cases was largely explained by the increase in virulence of the bacillus already referred to. A classical observation of Metchnikoff's illustrated this point: he injected anthrax virus into the two ears of a rabbit; in one ear a strongly active virus was used, in the other an attenuated brand. The attenuated virus caused cellular infiltration; the stronger virus produced serous exudation and hæmorrhages. This difference corresponded with that found in the lung lesions of the less and more severe cases of this epidemic. As regards secondary invasions, the pneumococcus, a hæmolytic streptococcus and *Staphylococcus albus* were those most frequently found.

---

[1] Proc. Soc. for Expt. Biol. and Med., vol. xx., No. 4, 1923.

Summing up his observations, Prof. Adami considered the following postulates justified: (1) One agent and one only was primarily responsible for the cases of the pandemic; (2) this agent was the influenza bacillus; (3) in the majority of cases other organisms invaded the lung and were responsible for many of the conditions found in fatal cases. He considered that pathologically the cases studied presented a characteristic series of changes which in their totality, in their succession and association, were specific and peculiar to this one disease. He especially emphasised, in this series, acute tracheitis characterised by denudation, and acute bilateral bronchitis and bronchiolitis, with purulent exudation in the milder cases, sanguineous in the more virulent, with comparatively little involvement of the air-cells. Prof. Adami concluded by pointing out how closely Nothnagel's account of the pathology of the great epidemic of a generation ago corresponded with our later findings.

Mr. Stephen Paget contributes an introduction to "Medical Practice in Africa and the East," which is about to be published by the Student Christian Movement. The book is a series of open letters on professional subjects from doctors practising abroad, addressed primarily to their colleagues at home.

Modern Technique in Treatment.

A Series of Special Articles, contributed by invitation, on the Treatment of Medical and Surgical Conditions.

XIII.

THE TREATMENT OF ECLAMPSIA.

THE treatment of eclampsia adopted in the Rotunda Hospital, Dublin, is aimed at the elimination of a toxin. The treatment is the same whether the patient is before labour, in labour, or post partum. The occurrence of eclampsia without preceding symptoms is extremely difficult to accept. I have never seen a case of eclampsia in which the urine had been examined previous to the onset of fits and found free from albumin. It is quite impossible to dissociate the eliminative treatment of eclampsia from the treatment of toxæmic albuminuria and the advanced stage of this, known as the pre-eclamptic state. The treatment may therefore be divided into three parts, none of which should be called prophylactic; this term is only applicable to the treatment of patients in the normal pregnant state so as to prevent the development of toxæmia of which eclampsia is only a terminal feature.

Toxæmic Albuminuria.

Whenever even a trace of albumin is present in the urine of a pregnant woman, the patient is put on a saline laxative in sufficient dosage to maintain a free action of the bowels twice or three times in the 24 hours. All meat diet is stopped and other diet reduced to a minimum for a few days. The patient must drink two or three pints of water daily. If the case is early the albumin will usually disappear in a day or two and the patient can be carried through pregnancy without a recurrence, if the diet, especially meat, be restricted, the bowels kept free, and a large water intake insisted on. Multiparæ respond less readily to treatment than primiparæ. In more advanced cases, when the urine is reduced in quantity, contains much albumin, and œdema is present, the patient is kept in bed, and all food stopped; saline purgatives are given eight-hourly until the bowels act several times a day, and then sufficiently often to maintain two or three movements daily. The patient drinks six pints or more of water in the 24 hours. This is continued for several days, during which the urine secreted invariably increases rapidly to over 40 oz. per diem, the œdema disappears, and the patient is usually free from symptoms in two to four days, with normal or nearly normal urine. Diet is then started, beginning with a half pint of milk; tea may be given freely. If the improvement is maintained another half pint of milk and a slice of bread and butter are given in the next 12 hours, and next day milk-pudding is added and the milk increased to two pints; if no relapse occurs, the patient is allowed a restricted white diet through the remainder of the pregnancy, any relapse being actively treated on the first indication of failure of the renal function, as shown by diminution of secretion or albumen recurring.

The Pre-eclamptic State.

When the toxæmia has become profound the same line of treatment is followed, but if there is marked drowsiness, or if the patient happens to have started labour, she may be treated as if eclampsia had developed. A strict water diet may have to be maintained for eight or ten days. If there is marked improvement a very light diet may be allowed; the albumin is unlikely to disappear completely. The majority of cases, particularly the primiparæ, are within one to three weeks of term and labour may set in while active treatment is in progress. In these circumstances a strict water diet is essential and should be maintained for at least a day or two after delivery. If labour does not start a case can be carried on for three or four weeks on what is apparently a quite insufficient diet, or on water only for 14 days. Patients in the last two weeks of pregnancy may be allowed to fall into labour spontaneously, but otherwise it will probably be better only to carry a profound case of toxæmia over the thirty-eighth week and then to induce labour. The fœtus suffers no disadvantage. If the fœtus is dead, labour should be induced as soon as the patient is improved, before any attempt at diet is made. Multiparæ are likely to develop severe symptoms much earlier than primiparæ and to be less responsive to treatment. If the primary improvement is not maintained by strict treatment the pregnancy must be terminated without further delay. No case of toxæmic albuminuria which receives this treatment for 24 hours will develop eclampsia. Some may not improve sufficiently for the continuation of pregnancy to be contemplated, but all will improve sufficiently for labour to be induced without hurry. All cases of severe toxæmia are best treated out of their own homes, since effective treatment entails starvation. Constant watching in a good light is essential so that the colour of the face can be clearly seen and cyanosis recognised immediately. A comatose patient makes no effort to clear the respiratory passages, if obstruction occurs; she merely becomes cyanosed and dies if the obstruction is not cleared in time.

Eclampsia.

The treatment of eclampsia is merely an adaptation of the treatment described above to suit the more urgent demands of the case. The first care is during the actual convulsion, to prevent injury to the tongue. If premonitory signs are noted something must be placed between the teeth before the tonic spasm develops; otherwise no attempt must be made to separate the teeth until the jaws relax at the start of the clonic stage, when a gag can be placed and retained during the spasm. The patient is rolled over slightly on her face so that all secretions run out of the mouth. Delay in beginning respiration when the clonic stage is over is due to obstruction, not to apnœa, and, therefore, if the patient does not spontaneously inspire, the chest should be pressed upon or the upper shoulder pushed back.

Posture.—The patient is put in the Sims position, with a single pillow under the head. If the patient moves she must be brought back to the lateral position when quiet or sleeping. Nothing should ever be given by the mouth until the patient is sufficiently conscious to drink from a cup.

Elimination of Toxins.

Gastric Lavage.—This is carried out on all patients, except those who are sufficiently conscious to drink freely and have not had a meal for over six hours. A large-sized stomach-tube is passed and the stomach washed out with bicarbonate solution, one drachm to the pint, until the return is quite free from gastric contents. Mistura sennæ co., with an extra drachm of sulphate of magnesia to the ounce, in a ℥iv. dose, or ℥iii. of castor oil, is then run into the stomach with about a pint of bicarbonate solution. If a fit occurs the mouth can be kept open with a gag and the lavage continued. Lavage is not required more than once, but if coma persists the tube is used to introduce a purgative and, in cases without œdema, the bicarbonate solution, until the patient can drink.

Colon Lavage.—The rectum is cleared of all solid fæces, a finger is passed in and the end of a No. 24 stomach-tube guided through the constricted portion of the gut between the second and first parts of the rectum. The tube is then passed for 14 to 18 inches. It will sometimes be found easier to pass the tube with the fluid running, and this should always be allowed once the constriction is passed. The bowel is then irrigated in and out with two to three pints of fluid at a time. At first the fluid returns slowly bringing some fæcal material; it then becomes clearer and after a period returns more or less in gushes through the funnel which is better not inverted. This will almost immediately be followed by a great increase of fæcal material and the irrigation is continued until the fæcal material begins to disappear. The fluid is then changed to bicarbonate solution and the irrigation continued until the return is clear, when two pints of solution is run in and four ounces of purgative and the tube withdrawn. Colon lavage is repeated in five or six hours, and will invariably bring away an enormous increase of fæcal matter, the result of the purgative given by mouth. In a few cases colon lavage is only required once, as the patient has recovered, but it will generally be better to repeat it. After the second wash out the bowels are likely to continue spontaneous action, and this should be looked for. In cases of profound coma or persistent fits colon lavage is repeated three and four times if spontaneous bowel action is not established and maintained.

Purgation.—The administration of purgatives is carried out by tube and continued after bowel action has begun. When the patient can drink, a purgative is given six or eight hourly until the evidence of toxæmia has completely disappeared.

Ingestion of Water.—Water to drink is given freely, from one or two ounces at first until six or eight pints or more are drunk in the 24 hours. Nothing but water is given until all the toxæmic symptoms are cleared up (except the albumin in the urine, which may be permanent); the secretion of urine must be copious before any sort of food is given. Invariably marked diuresis up to 150 to 250 oz. in 24 hours occurs from two to five days after recovery from eclampsia.

Poultices to the Loins.—The secretion of urine from the onset of fits is generally suppressed. If the small quantity usually found in the bladder is hæmorrhagic, if coma develops early, or fits persist over six hours, large linseed poultices are applied all over the back and continued until the secretion of urine is re-established to at least 40 oz. in 24 hours.

Submammary Infusions.—In cases with little or no œdema, bloody urine, vomiting, or profound coma without many fits, submammary infusion of bicarbonate solution is adopted. Forty ounces of fluid are run under the breasts at the time of the second colon lavage and may be repeated in six to twelve hours.

Morphia.—During the last two years I have ceased giving morphia. When a patient comes into labour and the coma is light there may be considerable restlessness and control may be difficult; a quarter grain of morphia then does good.

Other Medication.—When cyanosis is present oxygen is indicated and the heart requires watching as the cyanosis is usually due to cardiac debility more than pulmonary inefficiency. Strychnine and digatilin are thus indicated.

Termination of Labour.—When a case is in labour the advance is noted by palpating through the perineum, and when the head is felt in the vagina, if delivery is not rapidly spontaneous, forceps are applied. The patient should be kept in the lateral position even in the third stage. Bleeding during the third stage should be treated as in a normal case. There is always risk of progressive or recurrent heart failure during the 12 to 24 hours after delivery.

Remarks.

During the past three years I have treated 40 cases of eclampsia, with four deaths. Two of these were, I am convinced, avoidable and due to accidental suffocation, the other two were due to cardiac failure, one setting in 26 hours after the last fit and 7 hours after delivery, the other dying undelivered six hours after the cessation of fits and when the coma was apparently becoming less profound. Comparing these figures with those resulting from other methods I am convinced that the method of treatment adopted at the Rotunda Hospital is the most satisfactory now at our disposal.

GIBBON FITZGIBBON, M.D., F.R.C.P.Irel.,
Master, Rotunda Hospital, Dublin.

Special Articles.

UNITED STATES OF AMERICA.

(FROM AN OCCASIONAL CORRESPONDENT.)

Reorganisation of Federal Health Administration.

A PLAN for the better coördination of the health activities of the Federal Government has been submitted by the Presidential physician, Brig.-Gen. C. E. Sawyer. A new department is suggested with the title "Department of Education, Health and Welfare" under the control of a cabinet officer, to change with the administration. It is presumed that his chief assistant will also hold temporary office. The various bureaus of the departments are, in this scheme, to be controlled by permanent civil servants. The health services of the army and navy excepted, all the various agencies of the federal government for health, education, and social service and the care of ex-soldiers are to be transferred to the new department intact, each with its allotted personnel and budget. An idea of the size of this projected department can be gained when it is stated that the Veterans' Bureau alone expends more than four hundred million dollars a year, and that it is charged with an army twice as big as the standing army of the United States. In the meantime the Postmaster-General has arranged with the U.S. Public Health Service that all postal servants shall be given free vaccination against small-pox, typhoid, or paratyphoid fever at any of the stations of this service throughout the country. The postal servants are also entitled to free medical examination.

Rural Health Centres.

In New York the State Health Department is again pressing for legislation that will establish rural health centres throughout the State. The Bill is sure to meet with severe opposition, although the centres would be a great boon to rural communities and an extremely valuable example to this and other countries. Recently the death from diphtheria of a man aged 39 was reported to the State Department. The attending physician, although he saw the case on the date of the first symptoms, ten days before death, refused to give antitoxin. This physician is the only doctor within a radius of 15 miles. A similar incident, when four children died from diphtheria, occurred a month earlier. One can understand the anxiety of those, who wish to prevent such catastrophes, for an adequate rural service such as the proposed health centres would supply. So far as purely preventive work is concerned the department is able to do a good deal through travelling clinics and local campaigns. Their activities in diphtheria prophylaxis have been so successful that it is now estimated that one-half of the 64 per cent. of "non-immunes" in the school population have been protected. This should make a definite impression on the diphtheria morbidity rate.

Public Health Service.

Health education by radio is also continuing. Dr. H. M. Biggs wisely insists that only those who can speak with authority shall give official advice to the public across the ether. The list of speakers includes such well-known names as Victor C. Vaughan, of the National Research Council; Simon Flexner, of the Rockefeller Institute; Milton J. Rosenau, of Harvard; Haven Emerson, of Columbia; and G. E. A. Winslow, of Yale. From other States there comes news of progress along established public health lines and also of some rather original experiment. In South Carolina, where 725 people have had anti-rabic treatment during the past year, and three have died of rabies, it has been decided that the disease shall be attacked in the dog—not by muzzling, but by compulsory inoculation. A Bill to this end has been introduced into the State Assembly.

Influenza.

Influenza is still very prevalent, and on the authority of Surg.-Gen. Cumming this prevalence amounts to an epidemic. The epidemic, however, is less extensive than that of 1920 and the case mortality rate is low. Meanwhile Olitsky and Gates have shown the presence of antibodies, apparently specific for *B. pneumosintes*, in the blood of convalescents. An agglutinin was found to persist in the blood as long as five months after the attack. Doubtless by next year we shall have a pneumosintes vaccine.

NOTES FROM INDIA.

(FROM OUR OWN CORRESPONDENT.)

Vaccination in Madras Presidency.

THE decline in the success rate of vaccination operations has been under the consideration of the King Institute staff for the last three years, and a report from Major J. Cunningham, I.M.S., director of the Institute, recently issued as part of a Government order, covers this period, and gives a review of the relative values of lanoline and untreated glycerine lymph in the Madras Presidency. The evidence in favour of glycerinated lymph as opposed to lanoline lymph is overwhelming; vaccinators are constantly demanding glycerine lymph in preference to lanoline. The Government review of the report gives clear indications of the steps which led up to this decision—a decision which will, no doubt, receive considerable opposition from some quarters—but before quoting the Government order it will be of advantage to give the following recommendations made as a result of the investigation :—

1. That untreated glycerine lymph be substituted for lanoline lymph as the routine vaccine lymph for the Madras Presidency as soon as the King Institute is in a position to prepare the total quantity of glycerine lymph required.
2. That the Director be empowered to make the necessary changes and obtain the extra apparatus required for this purpose.
3. That the question of a seed depôt to be situated in the hills be left over for the present until further experience of Nejland's method has been gained.
4. That, as the cessation of routine vaccination during the hot season appears to be beneficial, the present orders on that subject should remain in force.
5. That experimentation should be continued with a view to determining the best methods of removing extraneous organisms from glycerine lymph without destroying the potency of the lymph.

In his report on the vaccine section of the King Institute for 1918–19, Major Cunningham considered three factors :—

1. Adverse climatic conditions: Examination of the monthly returns of vaccination proved that the hot months are most unfavourable for vaccination.
2. The influence on the returns of a greater stringency in the examination and verification of cases, consequent on the reorganisation of vaccine operations introduced in July, 1917. Comparison of district vaccination returns disclosed the fact that the success rate in these districts which showed best results in the previous year dropped in 1918–19 almost automatically under a stricter system of verification, the only possible inference being that the results obtained in previous years had been dishonestly inflated.
3. The possibility of changes in the potency of the lymph: From an examination of this factor, Major Cunningham concluded that variations in the success rate must be due to adverse factors operating after the lymph had been despatched to its destination.

Late in 1919 Major Cunningham visited the vaccine institutes at Belgaum and Lahore in order to study more recent methods of lymph manufacture and purification. The resulting report laid stress on the extreme susceptibility of the vaccine virus to heat, and pointed out that the relatively high temperatures prevailing in the Madras Presidency for a considerable portion of the year greatly increased the difficulties experienced in producing a lymph which would retain its potency during transit to the districts. Major Cunningham also pointed out that excessive heat, such as that experienced during the hot season, prevented a good growth on the calf, and caused rapid deterioration and destruction of the seed lymph. He drew attention to the deterioration of lymph on keeping except at very low temperatures, the ideal to be aimed at being to issue and use the lymph immediately after manufacture. The lack of success with the Madras lymph was undoubtedly due in part to the destruction of the vaccine virus by the action of extraneous organisms which were not removed in the process of manufacture of lanoline lymph, the standard preparation issued by the King Institute. Three main recommendations were the outcome of Major Cunningham's deputation, namely :—

1. That a thorough trial with glycerine lymph sterilised by the chloroform method be made in the Madras Presidency.
2. That a seed depôt should be established on the hills or in some climate more favourable than Madras.
3. That routine vaccination in the hot weather be discontinued.

In the report on the vaccine section for 1919–20 Dr. Kesava Pai pointed out that the efficacy of vaccine lymph and the percentage of success varied inversely as the period of storage, and recommended that chloroformed glycerinated lymph should be substituted for the lanoline paste—at that time the standard preparation—but the pulp for the glycerine lymph issued was manufactured in July and August, two of the worst months of the year, with the result that the case success rate fell to 42·2 and the insertion success rate to 27·5. Major Cunningham then advised that routine vaccination be discontinued during the hot weather and, after consultation with the Public Health Department, the proposal was sanctioned. Having heard of a new method, introduced by Dr. Nejland, of the Java Medical Service, for rejuvenating and retaining the potency of vaccine lymph by passing it in turn through three different series of vaccinifer, the rabbit being used to produce lymph for the cow calf, and the cow calf to provide lymph for the inoculation of buffaloes, Major Cunningham experimented on these lines, and has been able for the first time in the history of the Institute to get good results with the buffalo, and retain the potency of the seed through the cold season. The present report presents a convincing array of facts to demonstrate the superiority, under the conditions prevailing in the Madras Presidency, of untreated glycerine lymph to lanoline lymph, alike in the success rate and insertion success rate, in the size and type of the vesicles produced, and in keeping properties. The conclusions are based on the results of over 632,000 vaccinations, of which 559,659 were vaccinated with lanoline and 72,719 with untreated glycerine lymph, and may be judged by the fact that the case and insertion success rates obtained with the latter exceeded those of the former by 13·5 per cent. and 27·8 per cent. respectively. Appended to the report are a number of tables of statistics, a series of graphs illustrating different points raised in the body of the report, and finally a number of photographs of the types of vesicle produced in children and in calves by the two varieties of lymph. It is obvious that the glycerine lymph diluted to 1 in 1500 gives better results than the lanoline lymph diluted only to 1 in 500. The report will probably be accepted as a distinct advance in our knowledge of small-pox vaccine.

Child Welfare in Madras City.

At a recent meeting of the Madras Corporation the municipal child welfare work was subjected to severe criticism by a medical municipal councillor, who alleged grave defects in the working of the scheme. The midwives, he said, were inefficient and inexperienced owing to indifferent training ; he therefore opposed the opening of another centre in Georgetown. Another medical councillor took the opposite view and said that if the midwives were inefficient the fact condemned the training given at the maternity hospital and not the midwives, who were undoubtedly better than the barber women. After considerable discussion the original proposition to appoint a lady doctor to supervise Georgetown centre was adopted. In connexion with the expansion of this work a successful child welfare exhibition was recently held in Madras city.

Madras, Feb. 29th.

CZECHO-SLOVAKIA.

(FROM OUR OWN CORRESPONDENT.)

Heliotherapy in Tuberculosis.

THE sanatorium for the treatment of tuberculosis in Prosecnice, which was recently opened by "Humanitas," a workmen's association, contains two novelties in sanatorium practice in this country. A clinico-climatological observatory has been installed under the direction of Dr. V. Skalák, superintendent of the sanatorium, and Dr. A. Mrkos, consultant meteorologist of the Ministry of Public Works; this observatory is especially equipped for research into sunlight and its effect on the human organism. Heliotherapy and open-air treatment are modified according to the recorded observations. Occupational therapy has also been introduced, as the patients come largely from the working class. A great improvement of discipline followed when the patients were employed in the house and on the premises. Later, patients helped in the garden and began to issue a sanatorium magazine. In view of the success of the experiment it is intended to introduce occupational therapy into other tuberculosis institutions. The Masaryk Anti-Tuberculosis League is planning to create a committee on occupational therapy and after-care of sanatorium ex-patients.

Government Public Health Lectures.

The Ministry of Health and Physical Education has started regular courses of lectures for its officials, to be held twice a year for four months, and occupying four hours a week. Attendance at these lectures is not obligatory, but the interest which is being shown in them exceeds expectations. In the spring course, series of lectures are given dealing with international public health movements, physical education in different countries, methods of public health education, new developments in sanitary engineering, &c. The intention of the Ministry is to keep officials in touch with public health progress and to prevent them from becoming merely administrative officers with no scientific interest.

Public Health in Carpathian Russia.

The Czecho-Slovak Red Cross has adopted an extended programme for public health work in Carpathian Russia, an autonomous territory connected by the terms of the peace treaty with the Czecho-Slovak Republic. The country is largely inhabited by Ruthenians, Slav people living between the Slovaks and Russians. The territory was formerly Hungarian crown land, and the local population was very much neglected. The recent world war raged near this territory and partly within its boundaries, greatly contributing to the poverty of the inhabitants. The Czecho-Slovak Republic had first to fight against severe diseases endemic in this part of Europe ; after two years' work small-pox and typhus were stamped out. The political changes have greatly modified the economic situation of this territory ; when the land was largely in the hands of rich owners the inhabitants of the mountainous parts were compelled to seek summer work in districts which now belong to Hungary. The American Relief Administration and Lady Muriel Paget's English mission fed the Ruthenian children for some time, but the three years' independence of the Czecho-Slovak Republic brought order and some prosperity into Carpathian Russia, and the foreign missions left the country. Last autumn, however, the Republic passed through an industrial crisis, and again there was privation in Carpathian Russia ; the Red Cross recently summoned a mass meeting in Prague, to explain the situation, with the result that public kitchens were opened in the necessitous areas, and many Ruthenian children were taken into Czech families to be cared for. Meanwhile, the Government's general economic and educational programme is proceeding, and the time is probably not far distant when the Ruthenian people, which was nearing partial extinction, will be entirely self-supporting.

VIENNA.

(FROM OUR OWN CORRESPONDENT.)

Present Position of the Austrian "Krankenkassen."

AT a recent meeting of the Medical Organisation of Vienna, Dr. Stritzko, President, reported the results of his recent investigation into the present position of the Krankenkassen (sickness insurance clubs) throughout the country, and into the attitude of the medical profession towards them. Membership of one of these clubs is compulsory for a large proportion of the population; the Insurance Act of 1888 provided that all employees of private firms must insure in this manner. The principal clubs are the Workmen's, the Apprentices', the Commercial, and the District Krankenkassen; there are numerous smaller organisations, but they have lately tended to become merged in the larger ones, with advantage to both parties. Domestic servants and farm labourers are also compelled to belong to a club. The medical profession in Austria have long endeavoured to modify the principle of compulsory membership, chiefly with a view to excluding the recipients of higher salaries and wages. Their efforts have hitherto been unsuccessful, for the administration of the Krankenkassen is largely an affair of politics; the leaders of political parties have seats on the directing boards, or control the latter from outside. At present the influence of the Social Democrats is predominant in nearly all the clubs; this fact led to the formation of the Medical Organisation, which, comprising 98 per cent. of the medical men in the country, was in a position to negotiate on an equal footing with any political party. When, after the war, economic conditions rendered it necessary for all State and municipal officials to be insured against sickness, the Medical Organisation carried the arrangements through in a manner satisfactory to all concerned. The organisation has established the principle of free choice of medical attendant from the list of those who have agreed to the conditions drawn up between the organisation and any particular institution; payment is according to work done, and the tariff of charges is regulated according to the fluctuations of the rate of exchange (which has now been stable for three months). The older Krankenkassen, however, adhere to fixed salaries for their medical officers; under the principle of free choice the officers of the newer associations are able to earn considerably more. Moreover, the number of persons who can be attended in private practice is undergoing a steady reduction; approximately 60 per cent. of the entire population is now insured. Of the remaining 40 per cent. the wealthier half patronise specialists only. The older Krankenkassen suffer from lack of funds and have to be assisted by the State; the fees in private practice cannot be raised, and many authorities are agreed that Austria is drifting towards "socialisation" of the medical profession—that is to say, national insurance, with no more possibility of private general practice.

Suicides in Vienna, 1922.

The annual number of suicides in Vienna, which in 1913 had reached the figure of 1534, showed a fall during the war to below 700 (1917), but rose again rapidly after peace was declared, being 1209 in 1920. In 1921 it fell slightly but rose again to 1189 last year (570 males, 619 females). Sixty per cent. of males who attempted suicide were successful, but only 27 per cent. of females. The oldest victim was a woman, aged 82 (death by poison), the youngest a 10-year-old girl, who hanged herself. Poverty and financial straits were responsible in only a few cases; disappointment in love, family troubles, fear of punishment, or disease, are more often the cause of suicide. Male suicides prefer what might be termed "active" means—rope, revolver, or railway engine; females more often employ gas, or seek death by drowning or by throwing themselves from a height. Poison is used by equal numbers of both sexes. Seasonal analysis shows that fewest suicides occur in the autumn; May and June contain about 30 per cent. of the total number.

March 15th.

The Services.

ROYAL NAVAL MEDICAL SERVICE.

Surg. Comdr. J. P. H. Greenhalgh is placed on retd. list at his own request.

ROYAL ARMY MEDICAL CORPS.

Lt.-Col. R. F. Ellery retires on retd. pay.

Maj. and Bt. Lt.-Col. C. W. Holden relinquishes the temp. rank of Lt.-Col. on ceasing to be empld. as Asst. Dir. of Hygiene.

REGULAR ARMY RESERVE OF OFFICERS.

Maj.-Gen. H. Carr, late R.A.M.C., having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY.

The undermentioned, having attained the age limit, are retired and retain their rank, except where otherwise stated: Lt.-Cols. W. K. Clayton, J. MacK. Harrison, C. J. Deyns, and E. J. Lawless; Majs. J. Hamilton, R. Y. Anderson, and J. Bruce (granted the rank of Lt.-Col.); Capts. R. W. C. Macdonald, G. L. Findlay (granted the rank of Maj.), J. W. A. Cooper, B. M. Young, A. W. W. Hayles, M. Scales, G. S. Thompson, S. Child, H. J. Blackler, G. A. Auden, A. G. Hendley (granted the rank of Lt.-Col.), J. C. S. Dunn, H. G. Magrath (granted the rank of Maj.), A. Rodger (granted the rank of Maj.), C. Webb, S. F. H. Everill, J. W. McIntosh (granted the rank of Maj.), T. W. S. Paterson (granted the rank of Maj.), and A. Mowat (granted the rank of Maj.).

General Hospitals: The undermentioned officers relinquish their commns. and retain their rank, except where otherwise stated: Lt.-Cols. T. Beattie and T. Gowans (Bt. Col.) (retains his rank); Maj. A. Parkin; Capts. M. A. Cassidy, G. A. Ewart, and C. Gouldesbrough.

The undermentioned, having attained the age limit, are retired and retain their rank, except where otherwise stated: Lt.-Cols. Sir R. W. Philip, Sir J. M. Cotterill, Sir T. K. Dalziel, C. W. Cathcart, F. M. Caird, R. Muir, and R. Stockman; Majs. Sir D. Wallace (Bt. Lt.-Col.), Sir G. A. Berry, Sir J. W. B. Hodsdon, H. Rutherfurd, D. Macartney, W. K. Hunter, G. L. Gulland, J. J. G. Brown, J. W. Downie, and A. M. Ramsay; Capts. A. A. S. Skirving (granted the rank of Maj.), R. A. Fleming (granted the rank of Maj.), E. Matthew, J. W. Dowden, E. W. S. Carmichael, D. C. Watson, A. Miles, A. L. Turner, J. Miller, H. G. Langwill, E. Bramwell, J. G. Cattanach, G. L. Chiene, and W. Guy (Bt. Maj.).

TERRITORIAL ARMY RESERVE.

Maj. C. W. Edwards, having attained the age limit, is retired and is granted the rank of Lt.-Col.

ROYAL AIR FORCE.

B. F. Haythornthwaite is granted a short service commission as a Flight Lt.

CHELSEA HOSPITAL FOR WOMEN: COMPLETION OF REBUILDING SCHEME.—Rather more than £30,000 are required for building and equipping a home for the servants and nurses, who are at present occupying half the wards in the hospital. This home was part of the original rebuilding scheme, and there is ample room for it in the grounds. Detailed plans are now being prepared by the architects, Messrs. F. H. Greenaway and J. E. Newberry, and it is hoped that the work, which is considered urgent by the King Edward's Fund, may be begun this summer. As soon as completed some 45 more patients will be received into the hospital, and it will be possible to arrange that some of these shall be of rather better means though unable to pay the high charges of nursing homes. A sum of £13,500 is still required.

Correspondence.

"Audi alteram partem."

L'AFFAIRE SPAHLINGER.

To the Editor of THE LANCET.

SIR,—I have read with great interest the correspondence which has appeared in your columns concerning Mr. Henry Spahlinger and his work, and I am taking this opportunity of briefly reporting four interesting cases, which have either been treated by me by Spahlinger's method, or been under my direct observation, during the past two years.

CASE 1.—A young man, aged 26, who was wounded in November, 1920, a bullet entering the right side of the chest at the base and passing across, the exit wound being on the left base; the rib was fractured on the left side. Tuberculosis was diagnosed at the end of December, 1920, and the patient invalided. He came under my observation at the beginning of 1921, and the condition at that time was exceedingly bad. He was thin; had considerable scattered disease in his chest, especially at the base of the left lung where there were many moist wounds; was spitting up a great deal of greenish-yellow sputum, containing large numbers of tubercle bacilli; was febrile, the temperature being generally slightly raised at night, and at frequent periods he would get a severe auto-inoculation, even though resting, the temperature rising to considerable heights and all the signs and symptoms being aggravated. Also his pulse was rapid, he was having night-sweats, and considerable digestive disturbance. He continued to go steadily "downhill" until August, 1922, when he commenced Spahlinger's partial serum treatment, taking the material both by the mouth and by intramuscular injections. This patient gradually improved. I saw him a few days ago, and the condition, as far as one could judge, was that of complete arrest of the disease; he had regained his general condition and weight, his temperature was normal, the sputum had almost disappeared, the pulse was slow, and the digestion was right again.

CASE 2.—A man, aged 28, who came under my observation about a year ago, with severe active spreading disease of the upper lobe of the right lung, and with a dry pleurisy at the base of this lung. He was thin, pale, febrile, had a rapid pulse, and much sputum containing numbers of tubercle bacilli; he was also getting constant night-sweats, the digestion was impaired, and he had no appetite. This patient was put on the ordinary routine at Montana, but did not improve until about six months ago, when Spahlinger's partial serum treatment was commenced. The patient began to improve, and at the present time the disease appears to be arrested; he has gained two stones in weight, the cough and sputum have practically ceased, the temperature is never raised even on almost normal exercise, and the digestion, appetite, and cardiac condition are all excellent.

CASE 3.—A young man, aged 22, tall, thin, and afflicted with tuberculosis of both kidneys of five years' standing. There is no doubt whatever about the diagnosis, as it has been confirmed by cystoscopic examination and catheterisation of both ureters. The symptoms consisted of frequent attacks of kidney pain, chiefly on the left side, and the passage of urine containing a large quantity of pus, in which tubercle bacilli have been found on several occasions. There was never any fever, but patient's condition was poor. A year ago he started the Spahlinger treatment, with surgical serum No. 5, injections of 2 c.cm. twice per week. About the same time he also began a course of sun-bathing, and has taken from time to time urotropin. During the past year he has made very great improvement; the kidney pains and sensations have almost ceased to appear, he has gained weight and strength in every way, and the urine is much freer from pus than formerly. The patient himself is a very firm believer in the efficacy of the Spahlinger injections, and attributes his return to comparative health to these. He is very anxious to begin another course as soon as material is available.

CASE 4.—Woman aged 27. In October, 1919, she first contracted tuberculosis, which was brought to light by a fairly large hæmoptysis. She had recently had a cough and lost a good deal of weight. She became worse, and developed the classical signs of active pulmonary tuberculosis—i.e., fever, tachycardia, night-sweats, cough, sputum, loss of appetite, and dyspnœa on exertion. In addition to this she developed pain in the pelvis, and tuberculosis of the ovaries and tubes was diagnosed; subsequently the appendix and left ovary were removed. The physical signs in the chest were infiltration of both apices, and pleurisy at the left base. She went to a sanatorium, but did no good. In October, 1921, Spahlinger's partial serum treatment was commenced, and from this day the patient slowly began to improve. She came under my direct notice in January, 1922, and at this time the physical signs in the chest were slight, quite dry, and not easy to elicit; the general condition was good, the temperature normal, and there was no cough or sputum. I have since seen this patient, and she is still improving in general health.

I quote these cases from among a number of others as being especially striking in that none of them was improving under ordinary treatment, and it was only when the Spahlinger injections were commenced that definite recovery began.

I am, Sir, yours faithfully,
BERNARD HUDSON.

Montana, Valais, Switzerland, March 22nd, 1923.

THE SURGICAL TREATMENT OF SEPTIC MENINGITIS.

To the Editor of THE LANCET.

SIR,—I agree with Sir William Milligan in his letter in your issue of March 17th that Mr. H. L. Martyn's communication challenges criticism by those engaged in aural surgical practice. I am convinced that Mr. Martyn's case comes under the category of serous as distinguished from septic meningitis. When it is remembered that the death-rate of serous meningitis is not more than 5 per cent., while that of septic meningitis is at least 95 per cent., the necessity for clearly differentiating between the two is obvious.

The first 25 years of my experience in hospital and private surgical work would have led me to agree with Sir William Milligan when he gloomily says that operation, or no operation, the treatment of septic meningitis, following septic middle-ear disease, is almost invariably unsuccessful, and fatal results ensue. My last five years' work, however, have led me to the much happier conclusion that by improved methods the treatment of septic meningitis is by no means to be despaired of. Success essentially depends upon the employment of active in contrast with passive drainage. I have had in all four cases under my special method of which three recovered. The fourth was fatal, as in my opinion the treatment was delayed too long.

My impression is that there are far more fatalities due to septic meningitis than are recorded. Mastoid operations are performed in a dirty field. I visited during one afternoon three different theatres in London where radical mastoid operations were being performed, and in each case the ear was full of purulent material, much of which was certain to be re-spread on the deeper parts as those became exposed during the operation. The only effective way to clear and prepare the ear for operation is by suction.

My experience is that if proper methods of cleanliness are adopted for a month on even the most septic ear, the necessity for more than half the radical mastoid operations now done will disappear. The measures that I advocate consist of active, positive, suction drainage as distinguished from passive, negative drainage by gauze strips and tubes. Should the necessity arise, the brain can be decompressed at the roof inner wall and posterior wall of the antrum and tympanum, and active suction drainage applied in these positions by means of specially constructed small bell-shaped suckers.

I am, Sir, yours faithfully,
WM. STUART-LOW.

Wimpole-street, W., March 22nd, 1923.

THE TRANSMISSION OF LEPROSY INFECTION.

To the Editor of THE LANCET.

SIR,—In the course of my Chadwick lectures on the Evolution of Epidemics in April, 1913, I said: "The enormous numbers of leprosy bacilli which are found in the skin of leprous patients suggests the possibility of transmission in some cases by biting insects."[1] This suggestion was fortified in the following year by experiments published by Honeij and Parker.[2] Sir Leonard Rogers, in his lecture on the Leprosy Problem,[3] has now made the same suggestion in explaining the general relationship between heavy rainfall and high leprosy incidence in hot moist tropical and subtropical districts. Among other conditions favouring infection, Sir Leonard Rogers mentioned a low stage of civilisation and hygiene, which agrees again with the statement I made in the same lecture, that "since the renal and intestinal excreta are crowded with bacilli which thus are carried without the body it is easy to realise that insanitation may play an important part."[1]

I venture to think that these two methods of the conveyance of infection from the leprous to the healthy will be found to cover most of the cases. Insanitation conveying bacilli from urine and fæces includes not only defective methods of disposing of excreta, but neglect on the part of those leprous persons who prepare food, to wash the hands after urination or defæcation. Naturally, it would only be among people who have no fear of lepers that leprous persons would be permitted to have anything to do with the preparation of food for others.

I am, Sir, yours faithfully,
J. T. C. NASH,
Medical Officer of Health, County of Norfolk.
March 24th, 1923.

HILUM TUBERCULOSIS.

To the Editor of THE LANCET.

SIR,—It is with pleasure that an opportunity is given of reading that some radiographers raise a note of warning against the diagnosis of hilum tuberculosis, as is done in the paper by Dr. Bernard Hudson and Mr. Percy Sutton in your issue of March 17th. Since there appears to be a degree of confusion in the minds of some clinicians regarding the nature of the objections raised by morbid anatomists against belief in the existence of hilum tuberculosis, perhaps you will allow me, Sir, to express my own confession of faith.

In the first place, no one can doubt that in young children a caseating tuberculosis of bronchial glands may result in acute or in subacute tuberculous infection of the lung. In the great majority of cases death quickly follows. In three instances, however, I have seen a calcareous mass in the lung of a child in proximity to the root, showing that even this form of tuberculosis may become quiescent. While this appears to be the case I have never seen tuberculous fibrosis originating in the root of the lung either in children or adults. Occasionally in children caseous glands may act like any other course of obstruction of a bronchus and lead to dilatation of divisions of bronchial tubes, associated with which may be a varying degree of fibrosis, but such a condition is a non-tuberculous fibrosis. It follows mechanical obstruction, and has no direct connexion with tuberculous infection.

As regards hilum tuberculosis in the adult, I do not believe that it exists, except possibly by what one may call an accident, such as one may describe tuberculosis almost, if not quite, limited to one lower lobe of a lung. I have seen three such cases, but never tuberculosis of the lung in the adult originating at the root of the lung. The idea that hilum tuberculosis exists, it seems to me, has arisen by associating a misinterpretation of shadows cast by normal structures with the knowledge that in young children a form of tuberculosis of the lung may extend from the hilus. The post-mortem room, I maintain, does not support this mental conclusion.

I am, Sir, yours faithfully,
THEODORE FISHER.
Thorpe St. Andrew, Norwich, March 21st, 1923.

DENTAL BOARD LECTURES.

To the Editor of THE LANCET.

SIR,—In response to numerous requests the Dental Board has decided to publish in one volume the following lectures on the Diseases of the Periodontal Tissues due to Infection in their Relation to Toxæmia. (1) The Patho-Histology, by Mr. J. Howard Mummery; (2) The Local Clinical Symptoms, by Mr. J. G. Turner; (3) The Bacteriology, by Prof. E. E. Glynn; (4) The Systemic Effects, by Sir William Willcox. These lectures involve a considerable amount of original observation and research by the lecturers, and will be suitably illustrated by copies of the slides exhibited on the epidiascope, some of which will be coloured. The volume will be bound in cloth, and the price per copy will be 2*s.* 6*d.* post free. Only a limited number will be printed, and orders, accompanied by the remittance, should be sent to the Registrar, the Dental Board of the United Kingdom, 44, Hallam-street, London, W. 1, without delay.

I am, Sir, yours faithfully,
GEO. P. BLIZARD,
March 23rd, 1923. Assistant Registrar.

THE LAWS OF THERAPEUTIC IMMUNISATION.

To the Editor of THE LANCET.

SIR,—Without decrying the truly exquisite fabric of Sir Almroth Wright's[1] research itself, it seems to me that in some vital points the St. Mary's code runs contrary to clinical experience. It is surely hardly legitimate to generalise upon a few experiments performed with serophytic organisms alone and on strength of these have us reject the autogenous vaccine for the stock. The fallacy of this is at once apparent if we consider the strains of *Bacillus coli* which run into some hundreds in point of numbers. A stock vaccine would presumably contain examples of each in adequate concentration. Its composition would be an achievement even for St. Mary's. Its dosage would be colossal to be in the least effective. In other words, the coli stock vaccine is useless.

But apart from this, the autogenous vaccine has been clinically established for many years as always and generally the vastly superior, and if, as one is forced to believe, the protagonists of the stock vaccine theory discount clinical evidence as much inferior to laboratory deductions (as in the preface to the last edition of the "Teat and Capillary Glass Tube") then, indeed, Sir, I submit the cart is before the horse. Over and over again the fallacy of ignoring the clinical side and being over-scientific has been shown to be an evil legacy of Victorian days and to be a danger to be most closely guarded against. The recent discussion upon renal and hepatic efficiency tests shows only too clearly the limitations of scientific methods per se. Neither must it be forgotten that Sir Almroth Wright has not yet proved or disproved anything at all as to the value of autogenous vaccines. He examples serophytic infections, which certainly are often amenable to stock vaccines, at any rate, the streptococci. The whole gamut is not thereby sufficiently exhausted to permit of generalisations of so far-reaching and dramatic a kind as our mentors would desire.

Sir Almroth Wright was countered twice (in advance) by Sir Clifford Allbutt when he described in my book a case of septicæmia cured by an autogenous vaccine. The case is described in detail. Dr. Crofton also adds counter evidence to other vital points. The new St. Mary's code should be recast nearer to clinical experience. The most important point in which it errs is the suggestion that a stock vaccine is superior to an autogenous one. This has been proved clinically on hundreds of occasions to be entirely untrue.

I am, Sir, yours faithfully,
A. GEOFFREY SHERA.
Clinical Laboratory, Princess Alice Memorial Hospital,
Eastbourne, March 24th, 1923.

Obituary.

PROF. CARL ARND.

Dr. Carl Arnd, who died suddenly of heart failure on March 8th, was professor of general surgery in the University of Berne and one of the best-known and most highly respected surgeons in Switzerland. He was born on June 14th, 1865, in Petrograd, the son of a Swiss merchant there, and was educated at Berne where he studied medicine. He received his surgical training under Prof. Kocher in the University Surgical Clinic. In 1902 he became tutor in surgery, and in 1904 succeeded Prof. Girard as chief of one of the non-clinical surgical sections of the Insel-Spital in Berne. In 1909 he received the title of professor and in 1919 he became prof. extraord. for general surgery. Prof. Arnd's numerous writings dealt chiefly with surgical technique, the treatment of surgical tuberculosis, and orthopædic matters. For years he had been a member of the Swiss, of the German, and of the International Society of Surgery, and lately a member of the Swiss National Committee of the latter. Arnd was an able and careful operator and possessed a wide knowledge in all surgical matters combined with excellent general culture especially in the literature of his subject, for he was a good linguist. In addition he was a sagacious man of high natural gifts, a good teacher, and an eloquent speaker. His modesty was apt to prevent him from taking the position to which his intellectual equipment entitled him. He possessed great driving force and employed this, apart from his routine work, in the fight against surgical tuberculosis and cancer. For his friends and colleagues his death is a great loss.

THOMAS ALEXANDER MURRAY, L.R.C.P.IREL.,

MEDICAL OFFICER OF HEALTH, WARRINGTON R.D.

Dr. T. A. Murray, of Penketh, Warrington, who died suddenly on March 21st, in his 62nd year, received his education at Manchester Grammar School, and studied medicine at Owens College and Manchester Royal Infirmary. He qualified L.R.C.P. Ireland in 1887, and began private practice at Penketh two years later. He was for many years a member, and for some time chairman, of the Warrington Rural District Council, to which authority he later became medical officer of health. During the war Dr. Murray was a medical officer at the Lord Derby War Hospital, and served as commandant of the special constables in the Penketh district. For some years he was secretary of the Warrington Panel Committee. Among other appointments he held those of chairman of the Pensions Board, member of the National Service Medical Board, medical officer to the Cheshire Lines Committee, and police surgeon for the Sankey area. In 1889 Dr. Murray married Miss Alice Gilbert, of Nantwich. His widow and two daughters survive him.

A friend writes as follows: "Dr. Murray was held in the highest regard by the members of the medical profession in Warrington and district. His essential fairness of mind, even temper, and good nature made him an admirable local secretary of the British Medical Association. His wide experience of public affairs, readily placed at the disposal of his colleagues, both those in practice and those holding official posts, made for satisfactory dealing with contentious matters which might otherwise have engendered undue difference of opinion."

Public Health Services.

THE FIRST ANNUAL HEALTH REPORT FOR 1922.

Dr. A. T. Nankivell is to be congratulated on the prompt appearance of his report for 1922. The borough of Hornsey is, he tells us, very largely a "dormitory town," consisting generally of good house property. There are no slum areas, but many houses built for the use of one family are now occupied by two or more families for whom the sanitary and cooking accommodation is not satisfactory. There are 12,000 more women than men in the borough, the excess being chiefly domestic servants. Up to the age of 15 the sexes are equally balanced, but between the ages of 25 and 35 there are over 50 per cent. more women than men.

Some of the principal statistics for 1922 were: Estimated population, 88,007; birth-rate, 15·5; death-rates per 1000 of the population from all causes, 11·2; from tuberculosis, 0·8; from cancer 1·6; from respiratory diseases and influenza, 2·2. Death-rates per 1000 births—infant mortality, 52; diarrhœa, &c., under 2 years, 2·2; maternal mortality from child-birth, 3·7. Of the 72 deaths of infants, 41 occurred in the first month of life. Dr. Nankivell submits a chart which shows that the infant mortality has been reduced by one-half since 1900, but that the infant deaths attributed to ante-natal causes have remained stationary, and he expresses the opinion that more ante-natal work is needed at the centres.

No cases of small-pox occurred in the borough. The menace of small-pox led to the circulation of a leaflet on the value of vaccination and the population is now better protected than it was. Hornsey now has the right to use 10 beds in the Uxbridge Joint Small-pox Hospital. A small school outbreak of diphtheria was satisfactorily checked by "swabbing" the class and isolating a carrier. One child, out of ten notified, lost its sight from ophthalmia neonatorum. Now that scarlet fever is so mild Dr. Nankivell is inclined to favour the use of the isolation hospital beds for diseases of a more fatal character.

The school report records no new schemes. Dr. Nankivell thinks just as the child welfare records are passed on to the school, so both child welfare and school records might be usefully passed on to the panel practitioner. Unfortunately, unless the child goes to a secondary school there is a regrettable gap of two years when the adolescent is without medical supervision. Dr. Nankivell notes no malnutrition among the school-children from insufficiency of food, but a certain amount due to improper food, such as sweetstuffs, pickles, and strong tea, and a further amount caused by late hours and want of rest. Milk has been given to a number of children at school with very satisfactory results, and Dr. Nankivell thinks it is better for a poorly-nourished child than malt and oil, which is apt to be taken home and shared by the whole family. Four children are operated on for adenoids and tonsils every Saturday morning at the school clinic. At the end of the year there was a waiting list of 58. Although the results were satisfactory, Dr. Nankivell would prefer these children to be kept in hospital for 48 hours after the operation.

A leaflet is issued to parents, urging the importance of making full use of the facilities for dental treatment provided for the children. Of 6600 children inspected by the dentists, no less than 4205 needed treatment, and of these 2089 actually received treatment during the year.

SUSSEX AND THE RED CROSS.—The Duchess of Norfolk, presiding at the annual meeting of the Brighton, Hove, Preston and Patcham Division of the British Red Cross Society, held at Brighton on March 21st, said that the Red Cross would always be wanted. Her ambition was that the Sussex branch should be ready for organisation in 48 hours, and the compilation of a register of every trained V.A.D. in the county would tend to that end. Awards were distributed including the Norfolk cup to Sussex 13, and a number of war-time badges, bars, and medals. The annual report of the branch chronicled work carried on at the Lady George Nevill Hospital, Hove, where patients from all parts of the county receive electrical and other treatments; 282 men were admitted during the year, there were 27,974 attendances and 47,997 treatments, and 117 remained on the books. The ambulance column carried 746 patients in the 12 months, the car mileage being 15,923.

Medical News.

UNIVERSITY OF OXFORD: *Radcliffe Travelling Fellowship.*—The trustees have elected Maurice Elgie Shaw, B.M., B.Ch., M.A., New College (and Guy's Hospital), to a Fellowship of £300 a year, for two years.

The Radcliffe Prize for 1923 has been awarded to Arthur Duncan Gardner, D.M. (University College), F.R.C.S., formerly Radcliffe Travelling Fellow in the University, for his researches in medical science.

UNIVERSITY OF LONDON.—At a meeting of the Senate held on March 21st Prof. A. V. Hill, F.R.S., was appointed as from August 1st next to the Jodrell Chair of Physiology tenable at University College. Dr. Hill was educated at Trinity College, Cambridge, where he was Third Wrangler, and obtained a first-class in physiology in the second part of the Natural Sciences Tripos. He was Fellow of Trinity College from 1910 to 1916, and in the latter year was elected Fellow of King's College. During the war he was director of the Anti-Aircraft Experimental Section of the Munitions Inventions Department and a member of the Inventions Committee. Since 1919 he has been professor of physiology in the Victoria University of Manchester.—It was resolved to hold a reception for the Sixth Triennial Congress of the Société Internationale de Chirurgie, which will meet in London next July.

UNIVERSITY OF BIRMINGHAM: *Clinical Board.*—A course of post-graduate demonstrations will be given at the General Hospital, Birmingham, on Tuesdays from 3.30 to 5 P.M., April–June, 1923, commencing on April 17th. The course will be given by members of the medical and surgical staff, and will include demonstrations on skin diseases; nervous diseases; surgical cases; chronic arthritis and its treatment; diseases of the rectum; diseases of the heart; diseases of the nose and throat; investigation of diseases of the stomach; common deformities of the feet; diabetes; and cases illustrating the varieties of nephritis.

UNIVERSITY OF DURHAM.—At recent examinations the following candidates were successful:—

THIRD EXAMINATION FOR DEGREES OF BACHELOR OF MEDICINE AND BACHELOR OF SURGERY.

Materia Medica, Pharmacology and Pharmacy; Public Health; Medical Jurisprudence; Pathology and Elementary Bacteriology.—Edgar F. H. Bell, Alfred H. F. Cole, Joseph Davis, William H. Denholm, Joseph F. Hedley, James Henderson, Gwendolen Jones, William G. S. Pepper, and Florence M. Smith.

THIRD EXAMINATION FOR LICENCE IN DENTAL SURGERY.

Anatomy, Physiology, and Histology, Dental Anatomy, Dental Histology and Dental Materia Medica.—Honours (Second Class): Leslie T. D. Heppell, Arthur T. Picton, and George A. Catcheside.

UNIVERSITY OF MANCHESTER.—The following resolution was passed by the University Council at its last meeting:—

"The Council have heard with deep regret of the death of Sir William Thorburn, Professor Emeritus in the University. They desire to record their sense of his great services as an administrator, a teacher and an investigator, his eminence as a surgeon and the whole-hearted devotion with which he sacrificed himself in the service of his country. His sterling integrity of character inspired respect in all his colleagues and students.

"The Council desire to convey to his relatives their profound sympathy with them in their loss."

The following appointments have been made: Lecturer in chemistry, Mr. Fred Fairbrother, M.Sc.; clinical lecturer in infectious diseases, Dr. D. S. Sutherland; honorary clinical lecturer in tuberculosis, Dr. R. W. Marsden.

At recent examinations the following candidates were successful:—

DIPLOMA IN PUBLIC HEALTH.

Part I.—Ada Furniss, R. M. Galloway, Simon Kelly, B. L. Lloyd, Hilda Pratt, Efime Ratner, and Gladys J. C. Russell.

Part II.—G. V. Ashcroft.

CERTIFICATE IN FACTORY HYGIENE.

J. W. Chadwick.

BRITISH MEDICAL ASSOCIATION: *Scholarships and Grants in Aid of Scientific Research.*—The Council of the Association is prepared to receive applications for research scholarships as follows: 1. An Ernest Hart memorial scholarship, of the value of £200 per annum, for the study of some subject in the department of State Medicine. 2. Three research scholarships, each of the value of £150 per annum, for research into some subject relating to the causation, prevention, or treatment of disease. Each scholarship is tenable for one year, commencing on Oct. 1st, 1923. A scholar may be reappointed for not more than two additional terms. A scholar may hold a junior appointment at a university, medical school, or hospital provided the duties of such appointment do not interfere with his work as a scholar. The Council is also prepared to receive applications for grants for the assistance of research into the causation, treatment, or prevention of disease. Preference will be given, other things being equal, to members of the medical profession and to applicants who propose as subjects of investigation problems directly related to practical medicine. Applications for scholarships and grants for the year 1923–24 must be made not later than Saturday, June 9th, 1923, in the prescribed form. The conditions of award are stated in the regulations, a copy of which will be supplied on application to the Medical Secretary of the Association, 429, Strand, London, W.C. 2.

GLASGOW POST-GRADUATE MEDICAL ASSOCIATION. Under the auspices of the Association, provision has been made for clinical teaching of medical practitioners during the summer months (May to October). The teaching facilities comprise (*a*) clinical courses, and (*b*) clinical assistantships. The clinical courses are arranged to suit the requirements particularly of general practitioners. A limited number of clinical assistantships are provided whereby graduates desiring opportunities for detailed study of special subjects may become attached to wards or out-patient departments, and may work under direct supervision of the physician or surgeon in charge. Intending students must enrol and pay their fees at the particular institutions concerned. Enrolment is limited to qualified medical practitioners. Further information will be supplied on application to the Secretary of the Association at the University, Glasgow.

HORSHAM HOSPITAL.—Owing in the main to the exceptionally wet winter it was not found possible to complete the erection of the new hospital at Horsham for the opening ceremony to take place in February, but it is hoped that this may take place in about five weeks' time. The total cost when completed will be nearly £15,000 for the provision of 30 beds and, including the value of the old Cottage Hospital erected in 1892, practically the whole of the money has been found, many of the donations commemorating the sacrifice of sons of Horsham in the late war. A very satisfactory state of affairs was shown at the thirty-first annual meeting of subscribers and friends on March 21st. There was a balance at the bank of £112, together with £400 on deposit; 231 cases had been admitted. The amount received from patients was £281, or £30 more than in 1921, and judging by the demands for the single ward in the old hospital there is no doubt there will be a big demand for the three private wards in the new institution, which will bring in a considerable income. With a view to raising money for the upkeep of the hospital it is proposed to adopt a voluntary contributory scheme.

ROYAL VICTORIA HOSPITAL, BELFAST.—The annual meeting of the hospital was held on March 23rd, the Lord Mayor being in the chair. The board of management stated in its report that the number of new cases seeking advice and treatment at the hospital during the past year was 30,000, or nearly 3000 more than in the previous year, while nearly 300 more cases were treated in the wards. In view of demands on the bed accommodation, caused chiefly by street casualties (which usually occurred in batches), 25 additional beds were put into wards which were capable of taking them without causing overcrowding. In this way a total of 346 beds was obtained. The daily average number of beds occupied was 318. The chairman, in proposing the adoption of the report, stated that a sum of over £52,000, or about £1000 a week, was required during the year to run the hospital. Prof. J. A. Lindsay, chairman of the board of management, seconding the motion, said that when the present hospital was opened in 1903 the population of Belfast was about 355,000; it was now probably approaching half a million. During that period of 20 years there had been very little increase of hospital accommodation in the city, so that Belfast was at present under-hospitalled to a dangerous degree. The board of management recognised its responsibility; plans for extension had now been adopted, including three new wards, giving 60 new beds, a considerable extension of the extern department, a new nursing block, with accommodation for 75 nurses, and a new mortuary. These extensions would set free much-needed accommodation for special departments. A building committee had been appointed, and the work would be begun with all possible promptitude. The estimated cost was £64,000, exclusive of equipment. These additions would involve a heavy increase in the annual expenditure, and the board appealed for a larger income. A satisfactory feature in the accounts was an increase of £1023 from pay patients. The appointment of a resident biochemist would be of much benefit to the hospital and to the medical school. Between 300 and 400 students were attending the hospital.

Dr. G. W. Paterson has been reappointed an Official Member of the Legislative Council of the Island of Grenada.

The Memorandum as to the Duties of Doctors and Dentists under the Dangerous Drugs Act, 1920, has now been printed and may be obtained, price 2*d*., through any bookseller or direct from H.M. Stationery Office.

Royal Institution.—The lectures after Easter will begin on Tuesday, April 10th, when Sir Arthur Keith will deliver the first of a course of four lectures on the Machinery of Human Evolution. On Thursday afternoons, commencing April 12th, Dr. A. O. Rankine will lecture on the Transmission of Speech by Light, and Sir William Bayliss on the Nature of Enzyme Action. The Saturday afternoon lectures will include two by Dr. Leonard Williams on the Physical and Physiological Foundations of Character, and two by Dr. Arthur Hill on the Vegetation of the Andes and the New Zealand Flora.

Irish Free State: Medical Service in the National Army.—Our Dublin correspondent writes: The terms of remuneration of officers of the Medical Service of the Free State Army were announced last week. They are as follows: Lieutenant, £1 a day; captain, £1 10*s*.; commandant, £2 2*s*.; colonel, £1000 a year; colonel, while holding rank of Deputy Director of Medical Services or Chief Sanitary Officer, £250 a year extra; major-general, Director of Medical Services, £1500 a year. It is stated that the above rates will become effective on April 1st, 1923, and that the engagements of all officers under these rates are for one year only, terminating on March 31st, 1924. The army authorities are wise in making only temporary appointments, since it is not possible at present to estimate the size of the army on a peace footing. It is the hope of the profession that when permanent appointments are being made they will be made on the basis of competitive examination. The present head of the Free State Army Medical Service, Major-General Maurice R. J. Hayes, is retiring. He only accepted the post temporarily in order to organise the Service, and there is no doubt that in the eight months he has held office he has done as much as was possible to make the Service efficient and of high professional standing. The name of his successor is not yet announced.

Royal Medical Benevolent Fund.—At a recent meeting of the Committee 38 cases were considered and £489 voted to 35 applicants. The following is a summary of some of the cases relieved:—

Widow, aged 53, of L.R.C.S. Edin. who practised in Madras and died in 1912. Applicant's youngest daughter requires training (aged 20) to enable her to earn her own living and the Fund is asked to help. Applicant is at present out of a post herself but hopes to get one shortly. Voted £15 in two instalments.

Widow, aged 74, of M.R.C.S. Eng. who practised in Middlesex and died in 1903. Through age and increased infirmity applicant is unable to accept hospitality to visit friends; other houses where welcome for long visit was formerly offered are now closed through their own reduced circumstances. Applicant is crippled with rheumatism and can only get about on two sticks. Total income £68. Rent £28. Voted £26 in 12 instalments.

Daughter, aged 67, of M.D. St. And. who practised in Cambridgeshire and Hertfordshire and died in 1872. Owing to age and having a delicate sister (aged 62) unable to earn sufficient to make ends meet. Earns about £35 by teaching and a little by the sale of fruit and poultry. This case is strongly recommended by the Governesses' Benevolent Fund. Voted £18 in 12 instalments.

Daughter, aged 65, of M.R.C.S. Eng. who practised in South Wales and died in 1873. Applicant suffers from bronchitis and has not been able to work since October, 1921. Nurse by profession. Failed in 1922 to get sufficient votes for Epsom College. Only income from Nurses' Insurance Fund, 7*s*. 6*d*. per week, and occasional gifts from friends. Sisters have been helped by the Fund. Voted £18 in 12 instalments.

Widow, aged 37, of M.R.C.S. Eng. who practised in Buckinghamshire and died in 1922. Owing to the sudden death of her husband she is left with two children, ages 10 and 8½, with an income of only £100 a year. Applicant asks for help towards education. A small grant was made to make the applicant eligible for the consideration of an education grant.

Widow, aged 32, of M.R.C.S. Eng. who practised in Kent and died in 1922. Applicant's husband was ill for eight years which prevented him from working and saving. She is left with a son, aged 6, and her only income is the interest on £900. As applicant is a trained nurse she hopes to take it up again. Rent £30. A small grant was made to make the applicant eligible for the consideration of an education grant.

L.R.C.P. & S., aged 73. Applicant has been unable to obtain any locums since October, 1922, and is asking the Fund to give him a little assistance. He has a married son, aged 24, who is a market gardener, and he has to give him assistance now and again. Rent is £70 a year inclusive, and only income last year was £160 from locums, nothing since October, 1922. Voted £26 in 12 instalments.

Subscriptions may be sent to the Hon. Treasurer, Sir Charters Symonds, at 11, Chandos-street, London, W. 1.

Parliamentary Intelligence.

HOUSE OF COMMONS.

Wednesday, March 21st.

Codification of Workmen's Compensation Legislation.

Mr. Sexton moved: "That in view of the confusion due to the existence of several Acts of Parliament dealing with compensation for injury to workmen, this House is of opinion that any Bill dealing with workmen's compensation introduced by the Government should contain provisions for codifying the law." Dealing with the various anomalies which he said arose under the present law, the hon. Member remarked that the six weeks' notice was still maintained, and so was contracting out. It was a pernicious doctrine, a delusion, and a snare. The man was insured and he was compelled to undergo a medical examination. The medical referee said that he was fit for light work and the judge reduced the compensation accordingly, in many cases to 1*d*. per week. It was all donkey work in the docks, and the result was that the man failed to fulfil his obligation under the order of the court.

Mr. Tillett, who seconded the motion, said they were anxious to force on the Government the work of codifying the law. He would not mind if they spent £1,000,000 on the lawyers, or an equal sum on the doctors. They were not there for economy so far as the doctor and the lawyer were concerned. They wanted to give both a fair and square chance and he believed that they would do justice to their professions.

Mr. Bridgeman (Home Secretary) said that in the Workmen's Compensation Bill, which the Government hoped to introduce very shortly, they would be able to make some improvements. After that Bill was passed they could devote their attention to some kind of consolidation or codification of the various measures affecting this branch of legislation. He had been surprised to find that the Employers Liability Act had fallen into disuse. In 1898, the year after it came into force, the number of actions under that Act was 1879; in 1908 the number had fallen to 405. In 1918 the number was 63, and in 1921, the last year for which he had figures, the number was only 27. That showed clearly that there were many more objections from a workman's point of view to proceeding under that Act than there were to proceeding under the Workmen's Compensation Act. He was entirely in sympathy with the intentions of this motion.

The motion was carried without a division.

British Morphia and Heroin.

Captain John Hay asked the Secretary for the Home Department the amount of morphia and heroin manufactured in Great Britain in 1921 and the amount exported; and what became of the balance remaining in the country.—Mr. Bridgeman replied: The figures according to the returns furnished to the Home Office are: Morphine manufactured, 147,790 oz.; exported 77,364 oz.; heroin manufactured, 12,385 oz.; exported 14,107 oz. To obtain the balance remaining and used in the country during the year, the stocks in hand at the beginning of the year would have to be added to the amount manufactured, and we have no figures to show these amounts, but apart from any supplies obtained illicitly in contravention of the Dangerous Drugs Act the balance would be disposed of for medical and scientific purposes through the wholesale or retail dealers licensed or authorised under the Act.

Telephone Mouthpieces and Disease.

Major Viscount Sandon asked the Minister of Health whether, if in the opinion of his department, disease was spread, as was alleged, by means of mouthpieces of telephones, he would have those in public call-offices disinfected.—Mr. Neville Chamberlain replied: I am advised that there is no definite evidence to show that disease is spread in this way. As the result of bacteriological inquiries made in this country and abroad some few years ago, it was held that the transmission of pulmonary tuberculosis through the medium of the telephone mouthpiece is practically impossible. In any event, the disinfection of telephone mouthpieces after each individual user would obviously be impracticable.

National Health Insurance Benefits.

Mr. William Graham asked the Minister of Health whether he had settled the conditions which would determine the title of members of Approved Societies to participate in schemes for additional national health insurance benefits following the second valuation by the Government actuary; if so, when would the conditions be published, and would Approved Societies be consulted on this point; and whether, if the conditions and consequent regulations had not been settled, the Ministry of Health would submit the proposals to Approved Societies through the Association of Approved Societies and/or the National Conference of

Friendly Societies for consideration prior to their receiving legal effect.—Mr. Neville Chamberlain replied: The matter referred to by the hon. Member is at present under consideration, and the views of Approved Societies of various types are being obtained, including those represented by the two bodies named in the last part of the question.

Feeding of Necessitous School-Children.

Major Kelley asked the President of the Board of Education whether he proposed to make any alteration this year in the provision for the feeding of necessitous school-children; and whether any special grant was to be made in relief of the cost of education in necessitous areas.—Mr. E. Wood replied: The answer to the first part of the question is in the negative. Following the practice of former years an additional grant will be payable in respect of highly rated areas.

"Reconstituted" Milk.

Mr. Albert Alexander asked the Minister of Health if his attention had been called to an advertisement appearing in a magazine called the *Milk Industry*, published by the National Federation of Dairymen's Association, offering for sale materials and machinery for the manufacture of reconstituted milk, the sale of which was prohibited by the Milk and Dairies (Amendment) Act, 1922; and, if so, whether he proposed to take any action in the matter.—Mr. Neville Chamberlain replied: Yes, Sir, my attention has recently been drawn to this advertisement and I am considering whether it is possible to take any effective action in the matter. But I would remind the hon. Member that the offence under Section 4 (2) of the Act of 1922 is to sell "reconstituted milk" as "milk."

The Agreement with Panel Practitioners.

Major McKenzie Wood asked the Minister of Health whether he could yet make any statement as to his proposals for a new arrangement with the doctors under the National Health Insurance Act to take the place of the present agreement, which expired at the end of this year.—Mr. Neville Chamberlain replied: I am not in a position to make any statement on this matter.—Major McKenzie Wood: Can the right. hon. gentleman say when he is likely to be able to make a statement?—Mr. Chamberlain: I am afraid I cannot give any definite date at present.—Dr. Watts: Is the right hon. gentleman aware that under the present agreement many doctors are expected to be on duty 24 hours a day and seven days a week.—No further answer was given.

Medical Officers at the War Office.

Mr. Becker asked the Under-Secretary of State for War how many medical officers are employed at the War Office; and were some of these doing ordinary secretarial work.—Lieut.-Colonel Guinness replied: Eleven medical officers are employed in the War Office. None are doing ordinary secretarial work.

The Spahlinger Treatment.

Dr. Watts asked the Minister of Health if any investigations had been made by his department as to the value of the Spahlinger treatment for tuberculosis; if so, what was the nature of the reports received; and, if no investigation had yet been made would he take steps at the earliest possible date to have a thorough investigation made, as had already been done by the United States of America and other foreign Governments.—Mr. Neville Chamberlain replied: The answer to the first part of the question is in the affirmative. All the evidence available as to the value of this treatment has been investigated by my department, and one of the medical officers of the Ministry visited Geneva last year, and, through the courtesy of M. Spahlinger, was enabled to examine certain cases of tuberculosis which had been treated by this method. The conclusions arrived at were that, although it is not yet possible to express an opinion upon the scientific value of M. Spahlinger's work from the bacteriological standpoint, the clinical results already obtained fully warrant further investigation as soon as a supply of the complete serum and vaccine is available. It is understood that no definite date can yet be fixed by M. Spahlinger for the production of a further supply even for the purpose of scientific investigation. I am most anxious to encourage further trial of the remedies in this country under expert observation as soon as a supply is available.

Dr. Watts: Is the right hon. gentleman aware that the lives of many people suffering from tuberculosis have already been saved by the use of this serum?—Mr. Chamberlain: I have stated in my answer that, so far as we have been able to test the results, they appear to be very satisfactory, but we have not yet been able to get sufficient data to enable us to come to a final conclusion.

Lieut.-Colonel Astbury: If I bring to the notice of my right hon. friend several cases which have been cured entirely by the Spahlinger treatment will he give further consideration to the matter?—Mr. Chamberlain: There is no supply of serum at present.

Colonel Astbury: Is the right hon. gentleman aware that M. Spahlinger is practically ruined by the cost of this serum and has no further funds to go on with in order to produce more?—The Speaker: The matter cannot be debated by question and answer.

Thursday, March 22nd.

The Cost of Naval Hospitals.

The House considered on Report resolutions agreed to in Committee of Supply in connexion with the Navy Estimates for 1923–24.

Captain Moreing suggested that economy might be practised in regard to the naval medical service. He said he had no doubt that the Admiralty would maintain vehemently that if a sailor were put into a military hospital he would surely die, and he had no doubt that their military colleagues would maintain the same in regard to a soldier put into a naval hospital. They could not, however, allow these jealousies to stand in the way of efficiency or of economy. Why did they want to maintain separate hospital accommodation in various towns? What they should do was merely to maintain the actual minimum which was necessary for the accommodation of the three services and expand those services from civilian resources in war time.

Mr. Amery (First Lord of the Admiralty), replying to the debate, said he could assure Captain Moreing that every endeavour was made to avoid overlapping in the naval medical service. There were a great many places where men of the navy were attended in military hospitals as, for instance, at Gibraltar, and others where military men were attended in naval hospitals as at Chatham.

The resolutions were agreed to by 218 votes to 124.

Schemes for the Blind.

Mr. Short asked the Minister of Health if he can state the number of local authorities which had created schemes for the benefit of the blind under the Blind Persons Act, 1920.—Mr. Neville Chamberlain replied: 135 local authorities out of 145 have submitted schemes under the Blind Persons Act, 1920, and I understand that five other authorities have schemes at present under consideration.

Medical Referees and Disability Cases.

Mr. Frederick Roberts asked the Minister of Pensions whether it was the practice, in the case of disabled ex-Service men certified by the Pensions Ministry medical referee as totally incapacitated by war service, and where the disability had been admitted by the Ministry as due to service, to pay a lesser rate than full pension in such cases; and, if so, could he give the reasons for such policy.—Major Tryon replied: In cases of disability accepted by the Ministry as due to war service, pension is always awarded at the rate approximate to the degree of disablement certified by the medical board by whom the man is examined. If, as I assume, the hon. Member has in mind claims based on deterioration, I would point out that in such cases the man is referred for examination by a medical referee, not for an assessment for pension purposes, but for a preliminary expression of opinion on the merits of the claim. If the medical referee supports the claim the man is then examined by the board whose assessment is accepted and acted upon, whether higher or lower than the estimate given by the medical referee.

Mr. F. Roberts: Is any notice taken of the opinion of the medical referee as to the man being totally incapacitated?—Major Tryon: Certainly, we do attend to the medical referee's opinion. In order to deal promptly with cases we grant an allowance to carry on with. The object is to enable us to deal with the claim of a man who has got worse; otherwise the man's claim would not be settled for a considerable time.

Ex-Service Men in Lunatic Asylums.

Mr. Aubrey Herbert asked the Secretary for the Home Department whether there were 6000 ex-Service men in lunatic asylums; and whether he would consider the provision of more suitable accommodation and treatment for these men.—Mr. Neville Chamberlain replied: On Jan. 1st last the number of ex-Service men in mental hospitals in England and Wales classed as Service patients and paid for by the Ministry of Pensions was 4532.

Mr. Collison asked the Minister of Pensions the cost of maintaining the 700 ex-Service men now in lunatic asylums; and what would be the additional cost of maintaining these men in private institutions.—Major Tryon replied: I gather that the hon. Member refers to cases in which the mental condition is neither due to nor worsened by service, and I would remind him that my department is not responsible for their maintenance. I understand, however, that the present average cost for maintenance of a patient in a county or borough asylum is 24*s*. a week.

Non-Service Doctors on Medical Boards.

Major Guy Paget asked the Minister of Pensions how many non-ex-Service doctors and how many ex-Service doctors were employed on the pensions medical boards in Glasgow.—Major Tryon replied: The total number of medical practitioners on the panel from which members of the medical board for this area are drawn is 172, of whom 85 per cent. are ex-Service doctors.

Appointments in Royal Army Medical Corps.

Lieut.-Colonel Fremantle asked the Under Secretary of State for War what number of candidates competed for appointments to the Royal Army Medical Corps at the last examination; what number of vacancies was advertised; how many candidates passed the examination; how many received commissions; what were the main reasons for this dearth of candidates; and how he proposed to remedy them.—Lieut.-Colonel Guinness replied: Fifteen vacancies were advertised for appointments to the Royal Army Medical Corps at the last examination for which four candidates competed and were all successful, subsequently receiving commissions. As regards the last two parts of the question, the examination, the first since 1914, was unavoidably held at the very short notice of one month. Before entering into speculation as to other reasons and remedies I think it will be best to see what are the results of an examination held under more favourable conditions.

British Legion and Medical Boards.

Mr. Ponsonby asked the Minister of Pensions whether he had received complaints from the Handsworth and district branch of the British Legion with regard to cases in which local medical boards had contradicted the decision of the pensions appeal tribunal when it had been in the applicant's favour; and whether the pensions appeal tribunal could, at the time of the hearing of an appeal, assess the disability so that the Ministry of Pensions could make the award accordingly.—Major Tryon replied: My attention has been called to the complaint referred to, which is, however, based on a misapprehension, as decisions of the pensions appeal tribunal are invariably accepted by my department. An assessment tribunal may, in confirming the finality of the award, increase or reduce it or they may simply decide that the case is not ripe for final decision. This does not necessarily mean that the tribunal disagree with the rate at which the man's disablement has been assessed, and steps are being taken to make this clear in announcing decisions of this nature.

MONDAY, MARCH 26TH.

Officer's Disability Pensions.

Mr. Parkinson asked the Minister of Pensions the number of officers of all ranks who were in receipt of disability pensions, giving the aggregate cost of same.—Major Tryon replied: The number of pensions now in payment by my department to officers is approximately 28,500, representing an annual value of about £3,100,000.

Mr. Parkinson asked the Minister of Pensions the number of officers in receipt of disability pensions whose pensions were reviewed during the period from Feb. 1st, 1922, to Feb. 1st, 1923, stating the number which were increased, decreased, or cancelled, showing, respectively, the amount of money involved by these changes.—Major Tryon replied: During the period mentioned some 30,000 pensions to officers were reviewed, after medical re-examination, as required by the warrant. Of these, 67 per cent. remained unaltered or were increased, while 33 per cent. were decreased or terminated. The result of these changes represented a net decrease in the annual value of the awards reviewed of approximately £345,000.

King's Cross Philanthropic Society.—Sir Bruce Bruce-Porter presided at the annual dinner of this Society on March 22nd at the Connaught Rooms, London, W.C., when nearly 500 members and their friends were present. An elaborate vocal and instrumental programme was provided. The object of the Society, which was established in March, 1885, is to relieve local distress, and during 1922 nearly £1600 were distributed. The membership now numbers 651, an increase of nearly 100 since 1920. In proposing the toast of the evening, Sir Bruce Bruce-Porter said that it was almost impossible for a State department, even in England, to have in it a human element, but there was no country in the world where voluntary effort took a greater part. The Philanthropic Society was the product of purely voluntary effort, and he hoped that its membership would grow and its work extend, for there were still a large number of people who required help, owing to the aftermath of the war. The President of the Society, Mr. R. W. Coan, responded, and in giving the toast of "The Chairman," Dr. A. Brown, honorary medical officer to the Society, paid a tribute to the public work of Sir Bruce Bruce-Porter. Dr. E. A. Gregg, in proposing the toast of "The Ladies," gave some striking examples of the philanthropic work done by women during and since the war.

Medical Diary.

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

WEST LONDON POST-GRADUATE COLLEGE, West London Hospital, Hammersmith-road, W.

Monday, April 2nd.—10 a.m., Mr. MacDonald: Genito-Urinary Dept. 2 p.m., Mr. Addison: Surgical Wards. 3 p.m., Mr. Simmonds: Surgical Out-patients.

Tuesday.—10.30 a.m., Dr. Paterson: Demonstration of Medical Cases. 2 p.m., Mr. Banks Davis: Nose, Throat, and Ear. 2.30 p.m., Dr. Pritchard: Medical Wards.

Wednesday.—2 p.m., Dr. Burnford: Medical Wards. 2.30 p.m., Mr. Donald Armour: Surgical Wards. 3 p.m., Dr. Pernet: Skin Dept.

Thursday.—2 p.m., Mr. Bishop Harman: Eye Dept. 3 p.m., Dr. Scott Pinchin: Medical Out-patients. 5 p.m., Mr. Simmonds: Surgical Out-patients.

Friday.—10 a.m., Dr. Drummond Robinson: Gynæcological Operations. 12 noon, Dr. Flett: Radiology. 3 p.m., Mr. Sinclair: Surgical Out-patients.

Saturday.—9 a.m., Dr. Burnford: Bacterial Therapy Dept. 10 a.m., Dr. Saunders: Medical Diseases of Children. 10.30 a.m., Mr. Maingot: Surgical Pathology.

Daily, 10 a.m. to 6 p.m., Saturdays, 10 a.m. to 1 p.m., In-patients and Out-patients, Operations, Special Departments.

NORTH-EAST LONDON CLINICAL SOCIETY, Prince of Wales's General Hospital, Tottenham, N.

Thursday, April 5th.—4.15 p.m., Dr. J. Bright Banister: Obstetric Emergencies. (Followed by a discussion.)

QUEEN CHARLOTTE'S LYING-IN HOSPITAL, Marylebone-road, N.W.

Thursday, April 5th.—5 p.m., Mr. T. B. Davies: Displacements of the Gravid Uterus.

Appointments.

Adkins, Dulcie S., M.B., B.S. Lond., has been appointed Resident Assistant Medical Officer at the Boundary Park Hospital, Oldham.

Barritt, R. T., L.D.S. R.C.S. Eng., Honorary Dental Surgeon to the French Hospital.

Drybrough-Smith, E., M.D., Ch.B. Edin., F.R.C.S. Edin., Honorary Assistant Surgeon at East Sussex Hospital, Hastings.

Gowers, Dorothy W., L.R.C.P. Lond., M.R.C.S., Assistant Medical Officer, Borough of East Ham.

Joyner, C., M.B., Ch.B. Aberd., Assistant Medical Officer at the Derby County Mental Hospital.

Lowe, G. B., D.O. Oxon., L.R.C.P. Lond., M.R.C.S., Surgeon on the staff of the Royal Eastbourne Eye Hospital.

Newsholme, H. P., M.D., B.Ch. Lond., M.R.C.P. Lond., D.P.H., Medical Officer of Health for Croydon.

Patton, J., M.B., B.Ch., Resident Surgeon, Nottingham General Dispensary.

Certifying Surgeons under the Factory and Workshop Acts: Jones, J. H. (Lostwithiel); MacNaught, W. W., M.B., Ch.B. Glasg. (Shefford, Beds); Moir, J., M.B., Ch.B. Aberd. (Long Eaton); Sidebotham, F. N., M.D., B.Ch. Camb. (Ottery St. Mary); Whitington, P. P., L.S.A. (Tuxford).

Vacancies.

For further information refer to the advertisement columns.

All Saints Hospital for Genito-Urinary Diseases, Vauxhall Bridge-road, S.W.—Res. H.S. £200.

Bath, Royal Mineral Water Hospital.—Res. M.O. £200.

Bath, Winsley Sanatorium.—Asst. Res. M.O. £250.

Bedford County Hospital.—H.S. Also Asst. H.S. £175 and £130 respectively.

Birmingham and Midland Homœopathic Hospital and Dispensary.—Res. H.S. £175.

Bridge of Weir, near Glasgow, Consumption Sanatoria of Scotland.—Asst. Res. M.O. £250.

Brighton, Royal Sussex County Hospital.—Hon. P. Hon. Asst. P. Hon. Med. Clinical Asst.

Bristol, Cossham Memorial Hospital, Kingswood.—Res. H.S.

Derby Isolation Hospital and Sanatorium.—R.M.O. £400.

Derbyshire Royal Infirmary.—H.S. £200.

Dundee City.—Special M.O. for V.D. £600.

Gloucestershire Royal Infirmary and Eye Institution.—Surg.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. and Non.-Res. H.P. Each £150.

Hospital for Sick Children, Great Ormond-street, W.C.—H.P. £50. Also Surg. Registrar. £300.

Hull Royal Infirmary.—Sen. H.S. £200.

Lagos Town Council.—African Asst. M.O.H. £750.

Leicester Royal Infirmary.—Hon. Ophth. S.

Lincoln, Lindsey County Council.—Asst. Tub. O. and Asst. School M.O. £500.

Liverpool Open Air Hospital for Children, Leasowe.—Jun. M.O. £250.

London County Mental Hospital Service.—Seventh Asst. M.O. £440.

London Temperance Hospital, Hampstead-road, N.W.—Med. Reg. 40 guineas.

Maidstone, West Kent General Hospital.—H.S. £220.

Manchester, Ancoats Hospital.—Radiologist. £300.

Manchester Royal Infirmary.—Res. Surg. O. Also Asst. Res. Surg. O. £250 and £200 respectively. Female R.M.O. and Asst. R.M.O. £200 and £100 respectively.

Middleton-in-Wharfedale Sanatorium, near Ilkley.—Asst. M.O. £500.

National Dental Hospital, Great Portland-street, W.—Hon. Anæsthetist.

Norfolk Education Committee.—Asst. School M.O. £500.

Plaistow Fever Hospital.—Second Asst. M.O. £200.

Prince of Wales's General Hospital, Tottenham, N.—H.P. and H.S. Each £150. Jun. H.S. and Jun. H.P. Each £110.

Public Dispensary, 122, *Drury-lane, W.C.*—Hon. P. Also Res. M.O. £105.

Queen's Hospital for Children, Hackney-road, Bethnal Green, E.—Two H.P.'s. and H.S. Each £100. Also Asst. P. £1 1s. per attendance.

Rainhill County Mental Hospital.—Deputy Med. Supt. £350. Also Locum Tenens Asst. M.O. 7 guineas weekly.

Redhill, Surrey, Royal Earlswood Institution for Mental Defectives.—Jun. Asst. M.O. £250.

Rotherham Hospital.—Jun. H.S. £150.

Royal Northern Hospital, Holloway, N.—Cas. O. £150. H.P. £100.

St. Pancras Hospital, Pancras-road, N.W.—Jun. Asst. Med. Supt. £350.

Southampton County Borough.—Asst. School M.O. £500.

Staffordshire General Infirmary, Stafford.—H.P. £150.

Throat Hospital, Golden-square, W.—Hon. Registrar.

University College Hospital, Gower-street, W.C.—Hon. Ophthalmic S.

Willesden General Hospital.—Hon. Pathologist and Bacteriologist.

Wolverhampton and Midland Counties Eye Infirmary.—H.S. £200.

Births, Marriages, and Deaths.

BIRTHS.

AINLEY WALKER.—On March 23rd, at Charlbury-road, Oxford, the wife of Dr. E. W. Ainley Walker, of a daughter.

MARRIAGES.

BROWNE—PETERS.—On March 24th, at All Souls', Langham-place, Surgeon-Captain Robley Browne, O.B.E., Royal Navy (retired), to Mildred, daughter of Mr. and Mrs. Alfred Peters, Flackwell Heath, Bucks.

DEATHS.

BENSLEY.—On March 20th, at Cromwell-road, S.W., suddenly, Lieut.-Colonel Edwin Clement Bensley, F.R.C.S., I.M.S.

SIMMINS.—On March 23rd, at Upper Tollington Park, N., after influenza, Alfred George Simmins, M.B. Lond., B.Sc., late Temp. Surgeon-Lieut., R.N. (1914–19).

SIMMINS.—On March 23rd, at Upper Tollington Park, N., from heart failure, Anna Bella, wife of Alfred George Simmins, M.B.

SPENCER.—On March 17th, at the Victoria Hospital for Children, Tite-street, Chelsea, of pneumonia, Elfrida (Biddy) Spencer, B.A., M.R.C.S., L.R.C.P., dearly loved only daughter of Walter Spencer, F.R.C.S. and Elizabeth Spencer, 2, Portland-place, W.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

Notes, Comments, and Abstracts.

THE MYSTERY OF LORD BYRON'S LAMENESS.

Abstract of an illustrated Address delivered at a Social Evening of the Royal Society of Medicine on March 21st, 1923,

BY H. CHARLES CAMERON, M.D. CAMB.,
F.R.C.P. LOND.,
PHYSICIAN IN CHARGE OF THE CHILDREN'S DEPARTMENT, GUY'S HOSPITAL.

Dr. Cameron, after some introductory remarks, spoke of the widely spread unpopularity of Byron during his lifetime and of the intense interest which was taken in this question of his lameness. To the public of that day, said Dr. Cameron it seemed so right and fitting that this gifted and infamous being, whose face was of such amazing beauty, and whose life was so scandalous, should have, if not a cloven hoof, at least a club-foot. For charges of irreligion and immorality Byron cared very little. Indeed, I think that Byron was one of those persons, not uncommonly met with, who, with a kind of inverted hypocrisy, are at some pains to appear to the world considerably more wicked than they are. But on the question of his lameness he was exquisitely sensitive. In some notes of his childhood which he has left behind him he tells us how once that terrible mother of his, in one of her ungovernable fits of temper, called him "a lame brat," and how readily came his answer, "I was born so, mother." At Pisa, three years before his death, he wrote his tragedy, "The Deformed Transformed." The first words of the play are the mother's cry to her son, "Out, Hunchback!" and again the answer comes, "I was born so, mother." Byron never forgot it, nor did the British public which he had so offended and flouted.

Which Foot was Deformed?

Now the first point to which I would draw your attention is that his friends and his enemies alike showed a curious division of opinion as to which foot was deformed, an uncertainty which seems hard to explain if he suffered from club-foot in the ordinary sense of the word. Moore, his friend and biographer, Galt, the companion of his travels and also his biographer, Lady Blessington and the Countess Albruzzi, his intimate friends, never knew or could make up their minds which foot was lame. Gentleman Jackson, his boxing instructor, thought it was the left. His mother, who ought to have known, writing to Mrs. Leigh that she may obtain the advice of the great John Hunter, states definitely, "it is the right foot." Mrs. Leigh Hunt was of opinion that the left foot was shrunken but that it was not a club-foot. In THE LANCET for 1827–8 an instrument-maker, named Sheldrake, taking advantage of the public interest in the question, and not averse from a little self-advertisement, makes a long communication entitled, "Distortions of the Foot: Lord Byron's Case." He states that some 25 years before the fame of the cures which he was achieving in the treatment of club-foot reached the ears of Mrs. Byron in Aberdeen, and the boy was sent to London to consult him. By some mistake, however, we are told, he was taken, not to the genuine and gifted Mr. Sheldrake, but to an impostor of the same name practising hard by. It was not until many years later that, to his great chagrin, the poet heard of the deception which had been practised upon him in his innocent childhood. He at once journeyed to London to express to the real Mr. Sheldrake his sense of disappointment at having missed by so little the relief that might have been his. At this time the poet was just starting upon an Albanian tour, and all that could be done at the moment was to take a cast of the foot in plaster-of-Paris. Sheldrake appends to his article a crude woodcut of the grossest form of club-foot, such a woodcut as did duty in many an eighteenth century text-book, and claims that it represents a sketch made by him from this cast. It represents the left foot. Stendhal says the right foot. Thorwaldsen, when about to execute the statue of the poet now in the Library of Trinity, Cambridge, was told by Byron's intimate friend Hobhouse that the lameness was in the right foot. The Countess Guiccioli said the left. By the kindness of Mr. John Murray, the grandson of the publisher of the poet's works, we have here to-night two surgical boots made for Byron in boyhood. They are both for the right foot. They show that, whatever the nature of its incapacity, the right foot was not clubbed, but was long and very slender. I show you also the lasts on which Byron's boots were made. They were presented to the Nottingham Museum shortly after his death. There they were found in 1897 stowed away in a drawer with the original label still attached. And the plot begins to thicken for the lasts show feet which are well shaped and symmetrical.

Trelawny's Statement and Recantation.

In the year 1881 there was still living, near Worthing, Edward John Trelawny, in the eighty-ninth year of his age, the friend and companion of Byron and of Shelley. Of him Byron says with truly prophetic vision that he could not tell the truth "even to save his life." Upon the words of this old man a younger generation of the poet's admirers relied. In 1858 he published his celebrated "Recollections of Shelley and Byron." In it he describes his determination to satisfy his own curiosity and the curiosity of the public in the matter of Byron's deformity. To Missolonghi he hurried, to view the embalmed body of the poet, as it lay awaiting transport to England. He records minutely the steps which he took to carry out his indecent purpose. That he might be alone with the body he feigned faintness and asked Fletcher, the poet's valet, who was on guard, to fetch a glass of water. Then hurriedly he drew back the black pall and the white shroud and uncovered the feet and legs. "The great mystery was solved," he says, "both his feet were clubbed and his legs withered to the knee—the form and features of an Apollo with the feet and legs of a sylvan satyr." Surely, this was just what the public expected and wanted to hear, and that is what the public was told by Trelawny, the latest left of all his friends. But when Trelawny was a very old man, in his eighty-sixth year when his fame and responsibility as the sole surviving intimate of Byron had grown yearly greater, he republished his book with some additional matter and one striking alteration. In this passage we read again of the deception practised upon the watching valet, and of the uncovering of the poor dead feet: "I uncovered the Pilgrim's feet and was answered. It was caused by the contraction of the back sinews which the doctors call tendon Acchilles [sic] that prevented his heels resting on the ground and compelled him to walk on the fore part of his feet. Except for this defect, the feet were perfect." I think Trelawny found that he could not go down to the grave with the lie unrecalled and uncorrected and that he republished his book that he might ease his conscience.

Byron's Lameness not Extreme.

Byron's lameness, though obvious to all who met him, was not severe or extreme. It certainly did not incapacitate him from active exercise. It did not prevent him from playing cricket for Harrow against Eton in 1805, though he had someone to run for him, and though cricket, and even an Eton and Harrow match, was hardly the strenuous exercise which it has since become. Of his swimming prowess there is no doubt, if only for his celebrated swim across the Hellespont. He was in the water 1 hour and 10 minutes.

Was it Little's Disease?

What, then, was the nature of this extraordinary lameness, which embittered the poet's whole life, which aroused such unusual public interest and curiosity, which permitted such athletic success, and which seemed so elusive that though all his friends and relatives agreed as to its existence, an almost equal number located the fault in one foot or the other? Is it permitted to attempt a diagnosis 100 years after the death scene at Missolonghi? In that long space of time we have learnt much of the nature of injuries to the child at birth. Forty years after Byron's death, Little, the celebrated orthopædic surgeon, the founder of the Orthopædic Hospital, attended a meeting of the Obstetric Society and described in a communication, thereafter famous, a form of stiffness, rigidity, and incoördination which more often than not is confined to the lower extremities. Little's disease, as it has ever since been called, is caused by hæmorrhage on to the surface of the infant's brain, the result of some delay in the establishment of respiration at the moment of birth. That part of the cerebral cortex which presides over the voluntary movements of the legs is damaged. A child so injured walks clumsily and with difficulty, though the legs and feet are well formed. At rest or when asleep nothing amiss is apparent, but when a voluntary act such as walking is attempted, the limbs are gripped in a sort of rigid spasm, due to the failure of the antagonistic muscles to relax. In consequence the sufferer walks with a curious running gait, with a great appearance of effort, though only slow progress may be achieved. The body rises upon the toes and the knees are kept tightly pressed one against the other. I think that there can be no doubt that Lord Byron suffered from a mild form of this spastic paraplegia or Little's disease due to injury at birth.

We have conclusive evidence of abnormality of gait coupled with the proof that the feet were symmetrical and well formed. Of the character of the gait Trelawny alone attempts a detailed description. It is such that it accords with the assumption that Byron suffered from Little's disease and with that alone: "During his brief and brilliant career in London it was noticed by his friends that to hide his lameness he always entered a room quickly, running rather than walking, and stopt himself suddenly by planting his left (the comparatively sound) foot on the ground and resting upon it. On the rare occasions when he was seen walking in the streets it was observed that he moved with a peculiar sliding gait rather than the easy lounge of the fasionable saunterer—in fact with the gait of a person walking on the balls and toes of his feet and doing his best to hide the singular mode of progress." No inapt description of a person suffering from Little's disease.

It is characteristic of Little's disease that the sufferer learns by slow degrees and infinite pains to achieve a high measure of control over the limbs which are at first so stiff and wayward. In early childhood Byron was carried from doctor to doctor. He was treated in turn by John Hunter, Dr. Livingstone of Aberdeen, Matthew Baillie, Dr. Laurie of 2, St. Bartholomew's-close, as well as by the instrument makers, Lavender, of Nottingham, and Sheldrake of the Strand. By his thirteenth year all treatment seems to have been abandoned and we hear of no more visits to doctors. The poet himself repeatedly states that his lameness was caused at his birth. Of the actual circumstances of his birth we know but little, and that little is perhaps uncertain. Hanson, the family solicitor, is said to have bought the caul with which he was born at a house hard by this building, 16, Holles-street, Cavendish-square. He gave the caul to his brother, Captain Hanson, R.N. Perhaps because it was Byron's it brought none of its proverbial luck. Captain Hanson went down with his ship off Newhaven. Lastly it may be noted that Byron appears to have suffered at times during his life from epileptiform attacks such as are a not uncommon result of the cortical damage in Little's disease. With a local malformation of the foot there is no special liability to epilepsy.

I suggest to you that we have found the solution of the mystery which so agitated our forefathers, and found it in the back drawing-room of a little house, within 100 yards of this hall, where 135 years ago the baby Byron first, but too slowly, drew his breath.

A MEMORIAL TO THE LATE MR. A. W. BACOT.

Arthur William Bacot, F.E.S., entomologist to the Lister Institute of Preventive Medicine, died of typhus in Cairo on April 12th, 1922, while investigating this disease with Dr. J. A. Arkwright at the invitation of the Egyptian Government, and his work was the subject of a memorial address by Dr. Major Greenwood at a meeting of the London Natural History Society held at 40, Winchester House, London, E.C., on March 20th.

Arthur William Bacot, said Dr. Greenwood, was of Huguenot descent, delicate, and of a highly sensitive temperament. His attitude towards birds and beasts was sympathetic, and although he learned little of languages and science he had the faculty of seeing nature in a romantic dress. He started butterfly hunting at 5 years of age, and his delicate constitution kept him out of the City till he was 16, when he became employed in a commercial office. He joined the London Natural History Society and published several papers on subjects connected with lepidoptera, contributing largely to a monograph on the subject by the late Mr. Tutt. His work was characterised by much care and painstaking. One of the papers, describing observations on many generations of a moth made by himself and Mr. L. B. Prout, was published by the Royal Society and this brought him into touch with general scientific workers. Hence, in 1909, when the Advisory Committee on Plague in India was looking for a naturalist able to study the habits of the flea, Bacot was invited to undertake the bionomic investigation. His investigations in a garden shed at Loughton under conditions far from ideal were so good that he was subsequently appointed entomologist to the Lister Institute, where he at once responded to scientific environment and proper equipment. With Prof. C. J. Martin he made the brilliant discovery of the mechanism by which the flea conveyed infection in plague. Obscurity still reigns in regard to various factors of plague distribution—e.g., why plague introduced into a country such as our own (there had been a small outbreak in Essex) did not spread rapidly through the country? Bacot's opinion was that the success of an epizoötic in transferring itself to a human host depended upon the adjustment of small details only to be ascertained by a minute study of animal conditions.

The lecturer then went on to describe Bacot's careful search for a reliable agent for the destruction of fleas, which he found in naphthalene; his work on the yellow fever problem in West Africa, embodied in a masterly report issued by the Yellow Fever Commission; and finally, his war work. Bacot dealt, said Dr. Greenwood, with lice exactly as he had dealt with flies and mosquitoes. The virus of trench fever was shown to exist in the body of the louse, and this discovery opened the way to further progress. In the spring of 1920 he was asked to join the United States Red Cross Expedition to Poland and accepted the invitation although recognising the personal risk. During his work on rickettsia he contracted trench fever, and was much impressed by the inertia and mental distress caused by the illness, a fact insufficiently recognised when soldiers were the victims. Here he learnt Weigl's technique, subsequently modified by himself, in the rectal injection of blood in order to feed lice infected with typhus. Finally, Dr. Greenwood came to the tragic circumstances of Bacot's death, mentioning the fact that during his delirium he spoke only of his researches.

Dr. Millais Culpin, who moved a vote of thanks to the lecturer, emphasised the remarkable way in which Bacot emerged from the amateur to the professional research worker. It was all to the good, he thought, that Bacot remained uninfluenced by the somewhat necessary dogmatic teaching of science. His success had been due to his simple, straightforward, and unbiased methods of dealing with a subject. He never saw what was not there.

Mr. L. J. Tremayne, Dr. J. A. Arkwright, and Prof. A. E. Boycott also testified their admiration for Bacot's character.

In proposing a memorial to the memory of Bacot, Dr. Greenwood suggested that it might take the form of subsidising the teaching of natural history in elementary schools, a subject which had been very near to Bacot's heart.

THE MANUFACTURE OF MEDICAL BOTTLES.

THE recent controversy in the press relating to the capacity of medicine bottles has aroused interest in their manufacture. A visit paid last week to the new Charlton works of the United Glass Bottle Manufacturers, Ltd., has shown that in this, the largest bottle-making establishment in the country, no pains are spared to secure the greatest accuracy. The making of the moulds is a very highly skilled craft; capacity is estimated by water displacement, a solid wooden model of the bottle, and a "parison" or solid wooden model representing the cubic content of hot "metal" required, are used for this purpose; these are afterwards filed, together with the metal gauges made for use on the lathes, and all accessories, such as corks, labels, &c., enabling an order to be duplicated without difficulty at any time. The actual process of manufacture is fascinating. The sand and other ingredients are fed into furnaces and brought to a great heat by burning jets of vaporised oil; hand-blowing has been superseded, and beside each furnace revolves an Owens machine, a complicated and almost uncanny device, dipping its ten arms in turn into the molten glass, drawing up the exact quantity required, depositing it into the mould contained in each arm, and automatically blowing the bottle, all in one revolution of the machine. "Medicals," as medicine bottles are called, are produced by this method at a rate of 40 per minute. Still glowing, the bottles are passed down a trough to a lower floor, where they are set in annealing chambers in order that the strain may be taken out of the glass. After some hours in these chambers, the bottles are passed out and carefully inspected for imperfections before being packed for transport. The loss in breakages is a very small factor, so complete in every detail is the process of manufacture. Three continuous eight-hour shifts are worked, day and night, and millions of first-class bottles are turned out every year for the use of manufacturing chemists in this country, and to meet a large colonial and foreign trade. No doubt need be entertained concerning the accuracy of make and capacity of any bottle produced by this firm.

MILITARY SURGERY AND MORTALITY UNDER QUEEN ANNE.

"THE history of a soldier's wound beguiles the pain of it," says Sterne in "Tristram Shandy," but Uncle Toby, though he suffered much misery during four years, is made by his creator to tell us next to nothing about the manner of its treatment. According, indeed, to Mr. G. E. Gask's account of the care of the sick and wounded during the Marlborough campaigns of the year 1704,[1] we have scarcely any information as to how the wounded were treated. There were, of course, no anæsthetics, though opiates were used during operations, and military surgery probably "consisted largely of dressing wounds with various medicaments, probing them and removing foreign bodies, incising abscesses and amputating shattered limbs." Amputation was certainly performed, and we find Captain Windham, of Wyndham's Horse, writing light-heartedly to his mother on August 23rd (O.S.), 1704, stating that his leg was cut off "on Tuesday last was a fortnight." The decision to operate immediately preceded the operation, but we have no description of what must have been a simple affair, for it was followed by no ill-effects, and Captain Windham, probably on horseback, subsequently fought at Ramillies and Malplaquet.

The year of Ramillies (1706) was one of active political life. Not only did the great battle, with its 13,000 French dead, inflict a severe reverse on the ambitions of Louis XIV., but at home England and Scotland agreed upon the terms of their union, while science and literature flourished to such a degree that the period is referred to as the Augustan Age. John Evelyn died in 1706, honours were being showered on Sir Isaac Newton, Mead and Radcliffe were alive and active, and abroad Bayle died, while Leibnitz, Boerhaave, and a host of other great scientific names flourished. It is the more curious, therefore, to contemplate what may be called the ordinary give-and-take of medical knowledge in England at that time. The Bills of Mortality for 1706 take us back into the Dark Ages. "Within the limits of the Bill" the deaths recorded are often mysterious. They defy modern diagnosis. Four persons died of bleeding, six of bloody flux, four "bursten." "Chrisoms" took off eight, colick 101. Consumption was understood and 2716 died of it; deaths from fever, presumably typhoid—but we are not sure—numbered 2662. "Calenture" is counted separately and claims two victims. French pox numbers 47 victims, and small-pox 721. From old age died 1563, from apoplexy 64, from childbed 238, from convulsions 5961 (these may have been children), dropsy 742, diabetes 6, evil (King's evil) 60, fistula 22, flux 11, gangrene 6, gout 17, "great cold" 2, "grief" 7, "head ach" 1, "head-mould shot" 10, hooping cough 2, jaundice 87, imposthume 54, infants (? infantile ailments) 15, leprosy 1, lethargy 6, looseness 6, lunatick 26, malignant fever 2, measles 361, megrim 2, mortification 28, palsy 23, pleurisy 26, purples 9, quinsy 8, rash 3, rheumatism 29, rickets 206, St. Anthony's fire 8, scald-head 1, scarlet fever 4, sciatica 2, scurvy 5, shingles 1, spotted fever 54, stone 43, "suddenly" 68, surfeit 52, teeth 1185, thrush 38, "tissick" 251, tympany 11, water in the head 4, wen 1, worms 12. Gastric surgery being still unheard of, we find a fanciful list of illnesses, presumably internal, given as causes of death. Thus 6 persons died "livergrown," 1 died of "pain in the side," 56 of that puzzling ailment or complex "rising of the lights," 7 of rupture, 188 "stoppag'd in the stomach," 7 of strangury, 3 of "stronguillion," 7 of "twisting of the guts," 6 of "vomiting and looseness."

Despite the above formidable list the deaths in 1706 were not more than 19,847, and the decrease in burials amounted to 2250. The population of England at that time was about 6,050,000.

PUBLIC HEALTH IN MAURITIUS.

FROM a report prepared by Mr. L. Kœnig, Assistant Colonial Secretary, it is to be gathered that the ascertained population of the colony of Mauritius at the taking of the census in May, 1921, was 376,680. The birth-rate for 1921 among the general population was 39·7, and among the Indian population 37·5 per mille. The death-rates per 1000 in the two populations were 42·6 and 39·3 respectively. The number of deaths due to malaria and malarial cachexia (highest death-producing factors in Mauritius) was 3564. The next high causes of death were pneumonia and bronchopneumonia 2067, and influenza 1563. There were 291 deaths from plague. The epidemic started in May, reaching its maximum in November and finishing at the end of December. In the whole island 375 cases were recorded, of which 318 were in Port Louis. Enteric fever accounted for 288 cases and caused 28 deaths. The infantile mortality (deaths of children under one year) gave a ratio of 176·7 per 1000 births. There were 1623 still-births. A good start has been made with the work of training the necessary staff of midwives and also with general maternity work. During the year the number of cases treated in the public hospitals was 19,127, and in dispensaries 60,671, and there were 5066 outdoor cases, making a total of 84,864. At the Leper Asylum there were 43 patients when the year began (males 30, females 13). There were 15 admissions during the year, 11 deaths, and 10 discharges, 37 lepers remaining at the end of the year. A new leper colony is being erected a few miles out of Port Louis, and when it is completed the law compelling compulsory segregation of lepers will be brought into force. The climate of Mauritius is tropical, but, owing to the high elevation of the central plateau, a large part of the island enjoys a temperate and even bracing climate. The rainfall is irregular and varies according to the locality and elevation.

LYSOL.

WE are asked by Lysol, Ltd., Raynes Park, London, S.W., to call attention to the altered form in which their well-known disinfectant and antiseptic is now packed. Hitherto the bottles containing it have been sold in a wrapper. The firm now put up the bottles in a yellow carton, bearing a picture of a lysol bottle marked Marshall's Lysol.

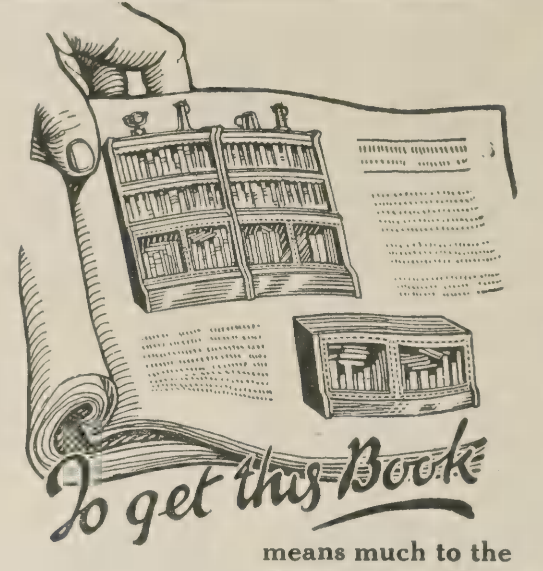
Bristol: JOHN WRIGHT & SONS Ltd. **London: SIMPKIN & CO. Ltd.**



means much to the
Medical Man

IT means knowing the real solution of the problem of keeping pace with the growing library. This Booklet, beautifully illustrated from real photographs, provides the reason for the unique popularity of the Oxford Sectional Bookcases: it makes clear their wide adaptability; shows why, although without equal for appearance, workmanship and permanent rigidity, they are the least expensive of all.

As we are not at the Ideal Home Exhibition this year, we strongly suggest a personal inspection at our London Agents—Messrs. Dulau & Co., Booksellers, 34/36, Margaret Street, Cavendish Square, W., or early application for descriptive booklet to—

WILLIAM BAKER & CO., LTD.

"Symptoms are the body's mother-tongue."

Cabot's
DIFFERENTIAL
Diagnosis

The best guide to the interpretation of symptoms.

"This book is a very interesting attempt to study and teach diagnosis from the point of view of the presenting symptom. It is a sustained effort of reasoning almost from the first to the last page, unencumbered by any exposition of technical methods. . . . For the young practitioner this book will prove of the highest value in guiding him on the narrow way that leads to correct diagnosis. It is scarcely less valuable to the experienced physician."—EDINBURGH MEDICAL JOURNAL.

Pneumothorax:
Cough, Fever, and a sudden attack of pain in the lower left axilla are the chief complaints.

SYMPTOM GROUPS: Vol. I.
Headache, general abdominal pain, epigastric pain, right hypochondriac pain, left hypochondriac pain, right iliac pain, left iliac pain, axillary pain, pain in arms, pain in legs and feet, fevers, chills, coma, convulsions, weakness, cough, vomiting, hematuria, dyspnea, jaundice, and nervousness—385 cases and 21 symptom-groups.

SYMPTOM GROUPS: Vol. II.
Abdominal and other tumors, vertigo, diarrhea, dyspnea, hematemesis, enlarged glands, blood in stools, swelling of face, hemoptysis, edema of legs, frequent micturition and polyuria, fainting, hoarseness, pallor, swelling of arm, delirium, palpitation and arhythmia, tremor, ascites and abdominal enlargement—317 cases and 19 symptom-groups.

Volume I.—Octavo of 781 pages, illustrated. Volume II.—Octavo of 709 pages, illustrated. By RICHARD C. CABOT, M.D., Assistant Professor of Clinical Medicine, Harvard Medical School. Volumes sold separately. Per Vol., Cloth, 42s. net.

Second Edition. **Beautifully Illustrated.**

DISEASES OF THE CHEST
and the Principles of Physical Diagnosis.

"The authors have endeavoured to teach as far as possible by means of illustrations, many of them photographs of frozen sections from the cadaver previously hardened in formalin. Indeed, the illustrations are one of the most striking features of the book, and form a most valuable and instructive series, well chosen, and well reproduced by the printer. The book may be warmly commended to the senior medical student, and it should be in the hands of all his medical instructors."—BRITISH MEDICAL JOURNAL.

Octavo of 782 pages, with 413 illustrations, 5 in colours. By G. W. NORRIS, M.D., and H. R. M. LANDIS, M.D., Assistant Professors of Medicine, University of Pennsylvania. Cloth, 45s. net.

Second Edition. **Thoroughly Revised.**

THE ROENTGEN DIAGNOSIS
of Diseases of the Alimentary Canal.

"The work is characterised by a thoroughness and accuracy well up to the high standard of the famous clinic with which Dr. Carman is associated. . . . A valuable feature is the description of those small details of manipulation of the patient during the examinations which will best bring out the points most useful in diagnosis. . . . The volume is one that cannot fail to be interesting and instructive to medical men who are actively working in abdominal disease from whatever point of view."—THE LANCET.

Octavo of 676 pages, with 626 illustrations. By RUSSELL D. CARMAN, M.D., Head of Section on Roentgenology Division of Medicine in the Mayo Clinic. Cloth, 42s. net.

Recently Issued. **Recently Issued.**

CLINICAL ELECTROCARDIOGRAPHY.

"Can be recommended as a safe introduction to the study of electrocardiography. The text is concise and lucid; the illustrations are well chosen and clearly reproduced; the bibliographical references are numerous and carefully selected."—EDINBURGH MEDICAL JOURNAL.

Octavo of 184 pages, with 186 illustrations. By F. A. WILLIUS, M.D., Associate in Section of Medicine, The Mayo Clinic, Rochester, Minn. Cloth, 25s. net.

Recently Issued. **New (3rd) Edition.**

DIAGNOSTIC AND THERAPEUTIC TECHNIQUE.

"In most text-books there is a felt want of detail in describing simple procedures of daily practice in hospital clinics. It is to these small details that Professor Morrow has turned his attention. In clear and concise language, with illustrations copious in number and clearly pourtrayed, he travels over the whole of medicine, surgery, and gynæcology, selecting those minor procedures so much of a routine to the specialist as to be taken for granted as understood."—EDINBURGH MEDICAL JOURNAL.

Octavo of 894 pages, with 892 line drawings, mostly original. By ALBERT S. MORROW, M.D., Attending Surgeon to the City Hospital, New York. Cloth, 40s. net.

BOOKS SENT, CARRIAGE PAID, ON RECEIPT OF PRICE.

The 12-h.p. ROVER SALOON, Price £775.

The variable conditions of road and weather at this season of the year impose severe tests upon the qualities of a car—but the 12-h.p. ROVER Saloon illustrated will prove its superiority. It may be purchased with every confidence to provide comfort in service and absolute dependability—real carriage comfort under all climatic conditions. Many improvements in the chassis have been effected for 1923, a new engine developing considerably more horse-power is fitted, giving greater liveliness and more speed to the car. The lubrication of the engine has been altered to pressure feed.

So far as can be foreseen at present there is not likely to be any further reduction in the prices of Rover cars during the 1923 season.

Send for Catalogue illustrating all Models.

A Bristol Doctor's Opinion of his 10-25 h.p. Charron-Laycock

"Such Surprising Power for so small an engine."

8/3/22

"My Charron-Laycock 10 h.p. has now done about 8,000 miles and I have much pleasure in writing to tell you how very pleased I am with her. I have owned and driven many small cars of about the same power, but have never encountered one which develops such surprising power for so small an engine. The springing is excellent, petrol consumption over 30 m.p.g., and another excellent feature is the almost total absence of skidding. I should like also to state that your promptness and kindness on offering advice and assistance make it a pleasure to own one of the products of your firm."

Copy of a further letter received, dated 14/10/22

"The car continues to give great satisfaction. I have never been so free from repairers' charges."

Intestinal Disinfection

No. 3.

ARTERIO-SCLEROSIS.

It is an old adage that a man is "as old as his arteries," meaning that degenerative changes in the arteries are largely responsible for senility.

The modern view is that arterio-sclerosis is produced by increased blood-pressure, and that increased blood-pressure results from the absorption of "pressor" substances developed by putrefactive bacteria in the intestine.

To retard the activity of the putrefactive bacteria, Metchnikoff introduced the soured milk treatment, but how much better it is to use an antiseptic substance. The ordinary so-called intestinal antiseptics, such as Salol, possess little real disinfectant power, and more potent germicides, such as Phenol, are absorbed and in sufficient dose are toxic.

The active principle of Kerol, besides being a very potent germicide, is not absorbed and is therefore non-toxic. The rational treatment of arterio-sclerosis would, therefore, include adequate intestinal disinfection by means of the keratin-coated Kerol Capsules.

For intestinal disinfection use KEROL CAPSULES (keratin-coated); they contain 3 minims of Kerol. One to three Capsules may be given three or four times a day after meals.

Please send for Literature and Samples, which will be sent free to any member of the Medical Profession

HAIR GROWTH BY NUTRITION

A Scientific Preparation for promoting the growth and preventing the loss of Hair

This remedy introduces a new feature into the treatment of hair troubles, such as greyness, loss of hair, and partial or complete baldness due to malnutrition. It is given internally in the form of tablets Its action is that of a specific nutrient stimulant to the growth of epidermal structures. Its claim may be gathered from the following quotations from leading medical journals.

"The Lancet," December 18th, 1920.

"Hair restoration by the use of special foodstuffs."

". . . N. Zuntz, the distinguished chemical physiologist of Berlin, takes a . . . . philosophic view as to the conditions likely to influence the growth of hair or wool. He recalls the fact that in the early decades of the nineteenth century the question was raised as to whether the woolly coat of sheep could be improved by the nature of the diet. Proceeding on the supposition that given an increased supply to the hair papillæ of the proximate organic material out of which is manufactured keratin—the organic basis of certain epidermic appendages—it might be possible to influence favourably the growth of wool and hair."

"Medical Press and Circular," March 7th, 1923.

"The introduction of this new remedy will certainly arouse a great amount of interest in the medical world, for its professed object is to act as a nutritional stimulant to the growth of human hair. This claim is supported by a volume of scientific testimony. Physiologists and scientific hair specialists have recognised the fact that the hair cannot be nourished by substances applied externally, but only by nutrients derived from the circulation. On these lines, after long and patient labour, Professor Zuntz produced the substances required for the specific nutrition of hair and nails. Zuntz found that it greatly increased the growth of hair in sheep, and other observers, later, have noted a similar result in rabbits.

"As the results of treatment must be necessarily slow, all we can say at present is that the remedy has been introduced in a scientific form and with excellent credentials. It is therefore worthy of extended trial."

PNEUMOSAN IN TUBERCULOSIS.

In every stage of Tuberculosis, where no impression can be made with routine or any other known treatment, use Pneumosan (Amyl-thio-trymethylamine), a homogeneous chemical substance, with a clinical record of 10 years. Pneumosan is well tolerated and has rapid inhibitory action; it is alterative and phagocitic. Well indicated in early and advanced cases and considered by a large number of Physicians to be the most reliable therapeutic agent in every type of Tuberculosis.

The Medical Superintendent of Birmingham General Dispensary writes: "During a period of 18 months I treated 103 cases of Pulmonary Tuberculosis. A large number were in a very advanced stage owing to the fact that Pneumosan was tried as a forlorn hope, where no other treatment seemed applicable. I obtained most striking results in early as well as in very advanced cases. A great point in its favour is that I have never known any untoward effect to follow its administration."

Pneumosan is issued in vials containing 20 injections at 15/6 and in boxes of 10 ampoules at 10/-.

Telephone No.: MUSEUM, 1191.

A Higher Percentage of Oil than other Emulsions

OVIOL

The Cod Liver Oil (52%) and Egg Emulsion.

WHEN INCREASED NUTRIMENT IS INDICATED YOU WILL FIND OVIOL MOST BENEFICIAL

In original bottles (approximately 9-ozs.) from all Chemists, Price 3/-

OVIOL contains 52% Norwegian Cod Liver Oil and fresh eggs.

The Vitamin content is computed as 125 times as rich as butter in the fat soluble Vitamin "A," and also includes the water soluble Vitamin "B," which is entirely lacking in butter or the usual cod liver oil emulsions.

Although the percentage of oil is so high OVIOL is most readily digested and of a really pleasant flavour which ensures its being taken regularly.

A Sample Bottle may be had on request from the Distributing Agents:

AN APPRECIATION OF THE MORLEY SELF-CONTROLLED AIR MATTRESS.

From Ancoats Hospital,
Ancoats, Manchester.

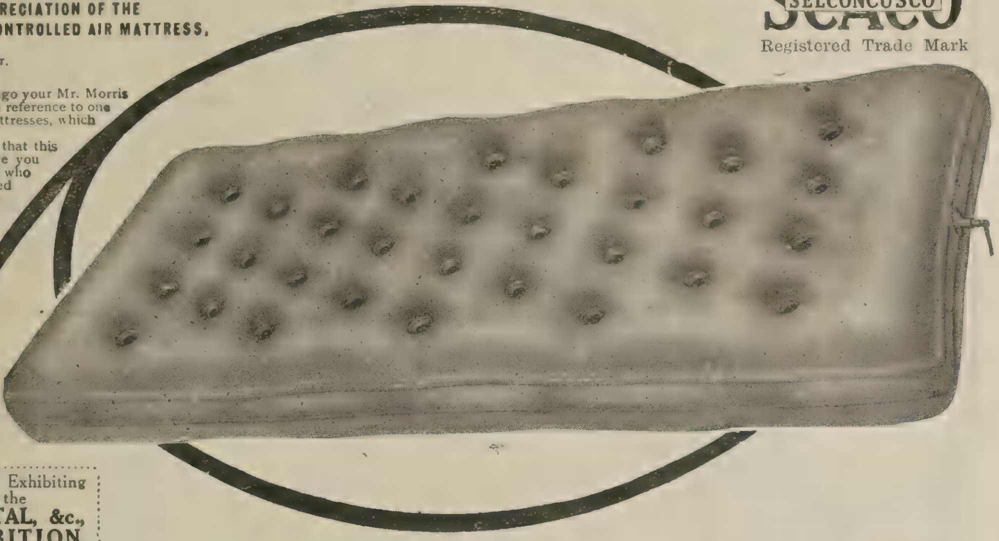
To SCACO, Ltd.

Dear Sirs.—About a month ago your Mr. Morris G. Roberts called upon [illegible] with reference to one of your Self-Controlled Air Mattresses, which you desired us to try.

You will be pleased to hear that this has been in constant use since you delivered it, and the patients who have been lying on the bed speak in the highest terms of the comfort and warmth which [illegible] gives.

The nurses also find it a vast improvement on the old-fashioned water bed, [illegible] it is much easier to handle, easily collapsible for putting away when not in use, and handier with regard to bed making than a water bed. We shall certainly replace our water beds, as they wear out, with your air mattress.

Y'rs faithfully,
H. J. D.,
Secretary.



We are Exhibiting at the
HOSPITAL, &c., EXHIBITION,
Central Hall, S.W.,
APRIL 3—7,
STAND
Nos. 26 and 27.

Perfect rest for the patient

Sleeping on the Morley Patent Air Mattress is just like sleeping on fresh air. Made from purest rubber, it is constructed as to give the utmost comfort whether lain upon in the centre, edge, or any other part. This absolutely hygienic mattress is remarkably light and can be washed, thoroughly dried and ready for use within half an hour, considerably lessening the work of the Hospital Staff. Think how favourably the absolute cleanliness of

Air-filled Chair Seats and air-filled Posh Bags for back and head rests contribute to the patient's comfort during convalescence. Their softness never varies and gives perfect rest and ease.

The MORLEY (*Self-Controlled*) AIR MATTRESS

compares with the old-fashioned mattress which absorbed and retained the moisture of the body. The Morley Patent Air Mattress weighs only 12 lb., lasts a lifetime, and gives more comfort all the time because the resilience is automatically regulated to every movement of the body.

Extensively used in Hospitals, Nursing Homes, where it has entirely superseded the old-fashioned water bed. As supplied to practically every institution in the country. Strongly recommended by the Medical Profession and Hospital Matrons. Sample beds willingly sent on approval.

Made by
THE SELF-CONTROLLED AIR CUSHION CO., LTD.,
Dept. C., Clifton Street Works = = Manchester.

London Sales Office DEPT. C., 408, SENTINEL HOUSE, Southampton Row, London, W.C.2. *Telephone: Museum 7530*

Made in all sizes and half sizes to suit any bed. The Morley Self Controlled Air Mattress is light, easily handled and cleaned. Is of practical convenience and comfort for use in ambulances.

JOHN BELL & CROYDEN, LTD., INCORPORATING **ARNOLD & SONS,**

50, 50a & 52, WIGMORE STREET, LONDON, W. 1.

THE HOUSE FOR EVERYTHING MEDICAL AND SURGICAL.

DAY AND NIGHT MOTOR DELIVERY.

A HOUSE OF TRADITIONS & IDEALS

The Service afforded to the Profession by JOHN BELL & CROYDEN, Ltd., INCORPORATING ARNOLD & SONS, 50, 50a, 52, Wigmore Street, London, W.

To ensure that the fullest possible effect is given to the skill and knowledge which the physician and the surgeon exert for the benefit of their patients, the co-operation of the services ancillary to medicine and surgery is pre-requisite.

The qualities of the specialist and the general practitioner must be supplemented by those of the expert pharmacist and the skilled manufacturer of surgical and clinical appliances and the innumerable adjuncts needed in the wide field of modern treatment.

It is the claim of the house of JOHN BELL & CROYDEN INCORPORATING ARNOLD & SONS that they are able to offer to members of the Medical Profession in London and the Provinces a service covering every branch of professional requirement—a service which they believe is unique in its completeness and unsurpassed in that essential feature—quality.

One hundred and twenty-five years ago, John Bell, father of the founder of the Pharmaceutical Society of Great Britain, established in Oxford Street the pharmaceutical business by which his name is perpetuated to-day. The "John Bell" traditions, enhanced by his illustrious son, have long been recognised as the standard to which all that is best in British pharmacy aspires, and these traditions still permeate every fibre of the vastly developed organisation now situated at 50, 50a, 52, Wigmore Street, W.

John Bell's Pharmacy had been in existence barely a score of years when, in another part of London, a concern of equal historical and traditional importance in its own sphere was instituted. The surgical instrument house of Arnold & Sons, a name known to the profession the world over, opened its doors in Smithfield in 1819, its founder being James Arnold. The fame of Arnold's surgical instruments and hospital furniture needs no more emphasis than does the pharmaceutical reputation of the house of John Bell & Croyden, Ltd., which evolved from the modest Oxford Street establishment of its earnest Quaker founder.

Both houses had, for more than a century, served the medical and surgical professions with unremitting loyalty. Comparatively recently circumstances rendered it possible for them to join forces, and by doing so, to afford a striking demonstration of the truth of the old adage "Union is Strength."

This fusion of interests and activities had led to remarkable results. Formerly, the surgical instruments and hospital furniture factory, showrooms, and warehouse of Arnold & Sons, and the pharmaceutical laboratories and works for the production of scientific glassware, sterilised ligatures, and aseptic surgical dressings of John Bell & Croyden, Ltd., were to be found in half a dozen quarters of London and its environs. To-day the entire manufacturing and distributive activities of the combined houses are concentrated under two roofs—the great factory and laboratory at Tottenham, and the pharmacy and showrooms in Wigmore Street, W.

This centralisation of energies has been attended by advantages which need no enlarging upon; increased powers of production, and a higher standard of efficiency are but two resultant effects.

The Tottenham factory, wherein are centralised the manufacturing activities of the united houses of John Bell & Croyden, Ltd., and Arnold & Sons is a building of tremendous capacity, which has been specially remodelled for the task it has to perform. Possessing a floor space of 120,000 square feet, the premises constitute a series of self-contained factories, each admirably adapted for its particular purpose.

Here the production of the whole range of Arnold's surgical instruments and hospital furniture (from a surgical needle to an operating table) is effected in its entirety.

On a separate floor is the galenical laboratory, where a trained and qualified staff prepares the pharmaceutical and pharmacopœial preparations required for use in the Wigmore Street pharmacy, and for meeting the demands of the innumerable physician and pharmacist clients of the House. Another department is devoted to the blowing of medical and scientific glassware, and there is also the laboratory wherein the "Marylebone" series of sterilised ligatures are prepared by a special process. Not the least noteworthy section of the building is the floor containing the airtight rooms in which, under the most stringently aseptic conditions, are manufactured the "Marylebone" sterilised dressings, a range of surgical requisites covering every requirement of this description likely to be called for in major or minor operations. The production of these sterilised dressings has become one of the most important features of the Company's activities. Closely allied to this department is another, wherein are produced the "Marylebone" series of sterilised accouchement outfits, which contain ready for instant use everything necessary for this all-important emergency.

The productive energies of the Tottenham manufactories and laboratories have their counterpart in the complete service offered to the profession by JOHN BELL & CROYDEN, Ltd., at their headquarters establishment at 50, 50a, 52, Wigmore Street, W. In these buildings, situated in the heart of what has been aptly called "London's Doctorland," is to be found what is perhaps the finest dispensing service in the capital. A staff of more than a score of qualified pharmacists are engaged in the dispensing of physicians' prescriptions, and, owing to the rigid system of control enforced, "dispensing errors" are, humanly speaking, impossible.

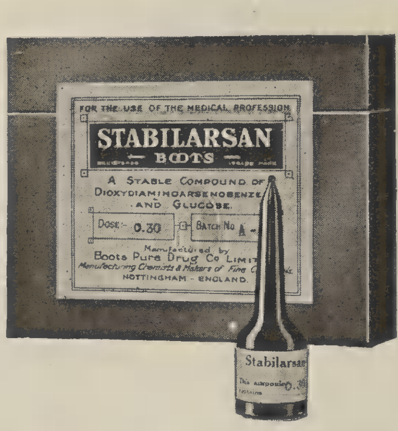
The resources of the "Finest Pharmacy in Europe" are, to say the least, remarkable. Here may be obtained every medical, surgical, pharmaceutical, and nursing requisite that may be required. Moreover, the service is a day and night one; the pharmacy is never closed, and the immediate delivery to any part of London at any hour of the twenty-four of medicinal or surgical necessaries, from a bottle of medicine to a fully-equipped motor ambulance, is an essential feature of the Company's service.

"Service" is the watchword of JOHN BELL & CROYDEN, Ltd., With an organisation modernised and rejuvenated to keep abreast of the unceasing march of medical, surgical, and pharmaceutical science, the House remains true to the ideals and traditions of those who founded its component branches a century, and a century and a quarter ago.

STABILARSAN—BOOTS

(Registered Trade Mark).
British Patent No. 177283 of 1922.

Approved by the Ministry of Health.



FOR THE USE OF THE MEDICAL PROFESSION
STABILARSAN
BOOTS
A STABLE COMPOUND OF DIOXYDIAMINOARSENOBENZE
AND GLUCOSE.
DOSE 0.30
BATCH No A
Manufactured by Boots Pure Drug Co Limit
Manufacturing Chemists & Makers of Fine C
NOTTINGHAM - ENGLAND.
Stabilarsan
0.30

A NEW chemical compound of Salvarsan and glucose; **low** in toxicity, **high** in curative power; the **greatest advance** in the simplification of—

ARSENOBENZOL TREATMENT

SUPPLIED in liquid form **ready for use,** the syringe being filled **directly from the ampoule.** STABILARSAN is **not** an untried specific. Prolonged clinical trials and exhaustive experimental investigations carried out during the last two years have given **uniformly excellent results.**

The purity and freedom from toxicity of all batches of STABILARSAN are accurately controlled by strict chemical and biological tests in our own laboratories before issue. The material is then finally tested and passed for sale by the Government Director of Biological Standards.

STABILARSAN is a product of British Research, is of British Manufacture, and is an invaluable addition to the armoury of British Medical Men.

MANUFACTURING CHEMISTS AND
MAKERS OF FINE CHEMICALS,

Station Street, NOTTINGHAM.

RATIONAL ORGANOTHERAPY.

NEURASTHENIA

and other

FUNCTIONAL NERVOUS DISORDERS

have, during the past fourteen years, been successfully treated by

THE LYMPHOID COMPOUND.

The professional demand for this preparation is to-day greater than ever because of the rapidity, completeness, certainty, and permanency of the recoveries obtained.

The product supplies a natural pabulum to the cells of the organism, in the form of scientifically prepared glandular extracts of maximum activity, which are synergic and never contra-indicated.

The Lymphoid Compound feeds and strengthens nerve cells, regulates metabolism, combats fatigue and exhaustion of body and mind, provides adequate compensation for loss of nervous energy, overcomes mental depression and enables the nervous system to function normally when treatment is discontinued.

FORMULA

Spermin and Extracts of Lymphatic Glands, Spinal Cord and Brain with Glycerophosphates of Iron, Sodium and Calcium.

Conveyed in soluble Gelatine capsules of gr. 4.

NOTE

More than 10,000 cases of Neurasthenia, Nervous Instability, Insomnia, Sexual Impotentia, Fatigue and Exhaustion and Mental Depression have responded with complete success to this, the original preparation.

Cost per dose 2½d. 50 Capsules, 10/-. 100 Capsules, 20/-.

A TYPICAL MEDICAL REPORT READS :—"I am glad to inform you that the Lymphoid Compound has been of immense benefit to my patient who had been a martyr to Neurasthenia for 12 years and in whose case all other methods of treatment had signally failed. He has made a splendid recovery. The Lymphoid Compound seems to me to be the long sought specific for this troublesome affection."—M.D. (Dub.).

THE LYMPH SERUM

(for hypodermic injection)

is also extensively prescribed by British Practitioners in

NERVOUS, MENTAL AND DEGENERATIVE CONDITIONS,

including

DEGENERATIVE CHANGES IN SPINAL CORD AND SPINAL NERVES, LOCOMOTOR ATAXIA, DISSEMINATED SCLEROSIS, SENILE DEGENERATION, SEXUAL IMPOTENTIA, NEUROSES, PSYCHOSES AND IN VASO-MOTOR and other affections of the SYMPATHETIC NERVOUS SYSTEM.

FORMULA

Spermin, Exts. of Lymphatic Glands, Spinal Cord and Brain, Bi-Chloride of Gold, Sodium Chloride, Lecithin and Nuclein.

Conveyed in Sterilised Ampoules of 5, 10, 15, or 20 minims or in vials of 500 minims.
Cost per 10 minim ampoule 1/9.

A TYPICAL MEDICAL REPORT READS :—

"My case of Locomotor Ataxia has improved far beyond my expectation. When I commenced with the Lymph serum injections I was not sanguine. My doubts are now dispelled. The patient has lost the lightning pains, the incoördination has gone, the gait is normal, there is a marked increase in body weight, and the disease has certainly ceased to progress. The patient has returned to work with practically none of the former symptoms remaining."—M.D. (Edin.).

Full information, interesting literature, and sample supplies (if desired) post free on application.

THE BRITISH ORGANOTHERAPY CO., LTD., makes a speciality of meeting the constantly growing demand by Medical Practitioners for Pluriglandular products to their own formulæ, for the treatment of special cases. These compounds are dispensed from fresh materials, at short notice, and at reasonable rates.

When Metabolism is Faulty

OVALTINE

TONIC FOOD BEVERAGE

Easily Digested, Readily Assimilated, Palatable, Soluble, Highly Nutritive, Essential Food Elements in Correct Ratio. Reasonable in Cost.

The above are the distinguishing features of this delicious combination of ripe barley malt, creamy milk, fresh eggs and the purest cocoa. A complete food, that reinforces the diet in a way necessary to ensure successful treatment.

A deservedly popular prescription in the dietetic treatment of tuberculosis, chlorosis, gastric or duodenal ulcer, nervous disorders, infantile marasmus, and convalescence after fever or operation. In agalactia 'Ovaltine' is a definite galactagogue.

A. WANDER Ltd., 45, Cowcross Street, London, E.C. 1.
Works: KING'S LANGLEY, HERTS.

Drawing of a wall painting in a Theban Tomb, depicting Egyptian ladies at a feast.

A liberal supply of 'Ovaltine' sent free to medical men in private or hospital practice.

Fandorine

for

Menstrual Disorders.

Prepared at CHATELAIN'S LABORATORIES, PARIS.

Active Principles	*Indications*
Ovarian and mammary extracts. Anemone pulsatilla. Piscidia erythrina. Viburnum prunifolium.	Uterine hæmorrhage, Fibromas, Puberty, Irregular or painful menstruation, Menopause.

Fandorine is an association of the substances of the two essential types of the genital glands, to which are added the active principles of anemone, and constitutes a specific for all diseases peculiar to women. It *regulates the functions*, arrests hæmorrhage and suppresses painful symptoms.

Fandorine should be taken by any woman who suffers from irregularities or painful symptoms. It is highly recommended for young girls at the period of formation, as well as for women at the critical age.

Fandorine is also highly recommended during the period of pregnancy and nursing.

THE

'Allenburys' Throat Pastilles

Glycerine & Black Currant Pastilles

Delicate in flavour. Efficient in use.

They are manufactured from pure glycerine and the fresh juice of choice ripe black currants by a special process which conserves the full value and flavour of the fruit. The 'Allenburys' Glycerine and Black Currant Pastilles have a demulcent and mildly astringent effect, most useful in allaying simple irritations of the throat. They dissolve slowly and uniformly, and have a delicious and slightly acidulous flavour.

Supplied in metal boxes containing 2 ozs., 4 ozs., 8 ozs. and 1 lb. respectively.

The 'Allenburys' Medicated Pastilles

may be relied upon to present the accurate amounts of the active ingredients and to be thoroughly effective in use. They dissolve slowly and uniformly, ensuring a thorough suffusion of the medicament over the mucous membrane. 81 varieties of the 'Allenburys' Medicated Pastilles are manufactured.

Packed in original tin boxes containing 3 ozs., 8 ozs. and 1 lb. respectively.

Descriptive Booklet and Price List sent on request to members of the Medical Profession.

'BYNIN' Amara

"A Distinct Advance on Easton's Syrup."

——*The 'Lancet.'*

'Bynin' Amara is an analogue of the well-known Easton's Syrup, but it is therapeutically much superior to that preparation. The syrup is replaced by 'Bynin,' pure active Liquid Malt, which affords a far better vehicle than the former, as it is actively digestive and nutritive. An added advantage is that the nauseous flavour of Easton's Syrup is effectively masked, whilst there is no possibility of sugar crystallising out and carrying down with it the active alkaloidal principles.

DOSE FOR ADULTS—A dessertspoonful to a tablespoonful in twice the quantity of water twice or on occasion three times daily.

Further particulars and free sample will be sent on request.

Allen & Hanburys Ltd.
37 Lombard Street, LONDON, E.C. 3.

Composition	grains
Quinine Phosphate	$1\frac{1}{2}$

Paraffinum Liquidum in Colitis

An Enterologist of international repute calls attention to the value of Paraffinum Liquidum in Colitis. In connection with such routine measures as proper diet, he finds that Paraffinum Liquidum aids greatly in soothing the irritated surfaces, and through softening the intestinal contents, helps to overcome the spastic condition of the intestine.

Chronic Colitis, dilatation of the catarrhal right colon, the whole viscus in irritation as shown by the excessive peristalses throughout Fermentative type of toxemia present.

From "Diseases of the Digestive System" by Anthony Bassler, M.D., F.A.C.P. Published by F. A. Davis Co., Philadelphia.

A NORMAL COLON.

NUJOL is highly efficacious in all types of intestinal stasis and resulting disorders. It is used in practice by many leading enterologists.

In determining a viscosity best adapted to general requirements Nujol Laboratories tried consistencies ranging from a thin fluid to a positive jelly. The viscosity adopted was fixed upon after exhaustive clinical test and research, and is in accord with the opinions of leading medical authorities.

That the value of Nujol to the Medical profession is generally recognised is attested by its use by physicians and in hospitals the world over.

Sample and authoritative literature dealing with the general and special uses of Nujol will be sent gratis.

For Constipation.

THE OLDEST THRONE IN EUROPE.—Modern archæological research constantly provides striking confirmation of ancient legends. Those relating to the power and splendour of King Minos are now being found to contain a considerable degree of historical truth. One of the most interesting archæological finds is a throne which we may fairly suppose to be that of the great king. It is of gypsum, as are also the benches round the chamber in which it is situated. The front of the seat is ornamented with a carved arch with mouldings, while its high back was originally covered with a decorative design. Fragments only of the frescoes which adorned the walls of the room now remain, but these have been restored in the present illustration with the help of other better preserved examples. A griffin—wingless and with a peacock's crest—is lying amongst tall grass. Undulations, representing water, are seen beneath—a very favourite decoration with the artists of this sea-girt empire. Among the debris in the Throne Room were found many signs of former splendour, such as fragments of gold-foil, lapis lazuli and crystal, blue and green porcelain, while upon the back of a crystal plaque was a fine miniature of a galloping bull, painted upon a blue ground.

COPYRIGHT

MENSTRUAL DISORDERS

A large proportion of the patients treated in a physician's practice are women suffering with some derangement of menstrual or generative function. These disorders are due in large measure to diminished or disturbed function of the glands of internal secretion. Owing to the reciprocal relationship that exists between these glands, a functional disorder of them is, in its last analysis, always a pluriglandular disturbance—never a monoglandular malady. As an eminent medical man puts it: "A woman is what she is on account of the sum total of her internal secretions."

Hormotone

which is a combination of thyroid (1/10 gr.), entire pituitary (1/20 gr.), ovary and testis, gives a physician the best of opportunities to prove the superiority of a pluriglandular product over the administration of ovarian substance alone.

Dose: One or two tablets three times daily before meals.

The Insufflation Treatment of Tuberculosis

In his book entitled "A Simple Treatment for Tuberculosis"* (which should be referred to for full particulars of the method) Dr. Owen F. Paget states that the insufflation of very small doses of finely comminuted dead tubercle bacilli gives results incomparably superior to those obtained by hypodermic injections. These results convince him that the epithelial cells of the ethmoid, superior turbinates and nasal sinuses are capable of forming antibodies which, conveyed to tissues at a distance, either neutralise the toxins of the bacilli or aid in the actual destruction of the latter.

Dr. Paget finds that the best preparation for insufflation is obtained by powdering the Tuberculin B. E. Tablets prepared by Parke, Davis & Co.

Mode of Administration.

The insufflator employed consists of a glass tube bent to a right-angle, one end tapering to a blunt tip and the other connected by a rubber tube with a pneumatic bulb.

The powder to be insufflated is poured into the wide end of the disconnected glass tube, gently tapping the latter to ensure that the powder lodges at the angle. The pointed end of the tube is then passed as high up the nostril as possible, the point being directed towards the frontal sinuses, not backwards towards the naso-pharynx. The rubber tubing being connected with the wide end of the glass tube, the powder is blown on to the region of the ethmoid and superior turbinates, by quick pressure on the rubber bulb.

Marked septal deflection, if present, must be rectified.

Dosage and other Considerations.

The doses which Dr. Paget employs are 1/6000 mgm., 1/500 mgm., or 1/40 mgm. of dried tubercle bacillary emulsion, according to the patient's condition. These doses are obtained by powdering and subdividing Parke, Davis & Co.'s Tuberculin B. E. tablets containing, respectively, 1/1000 mgm., 1/100 mgm., and 1 mgm. in each. (Tablets containing 1/10 mgm. are also supplied.)

In acute cases with high temperatures the risk of absorption must be avoided ; therefore minimal doses are employed. In old, unresolved and fibrotic cases, running low temperatures, larger doses are beneficial. The following procedure, based upon the experience of nearly 1000 cases, is suggested :—

(1) **With temperatures ranging between 100° and 105°, 1/6000 mgm. to be insufflated in each nostril, three times weekly.**
(2) **With temperatures ranging between 99° and 100°, 1/500 mgm. similarly.**
(3) **With temperatures ranging between normal, or sub-normal, and 99°, 1/40 mgm., similarly.**

The average chronic tuberculous case does quite well on insufflations alone, but acute cases must be kept in bed, and receive, in addition to the insufflations, treatment customary for any fever.

Should the temperature of a patient who is apparently doing well on a dosage of 1/500 mgm. or 1/40 mgm. suddenly rise two or three degrees consequent on over-exertion or hæmoptysis, a pause of 24 hours is recommended, after which doses of 1/6000 mgm. should be given until the attack has subsided. Periods of exacerbation and decline are to be expected in tuberculosis, and insufflations do not abruptly terminate them but gradually diminish their severity and frequency.

When the temperature has been at or about normal for ten days the patient may be permitted gradually increased movement and, subsequently, graduated exercise. After the sixth week of treatment, exercises in nasal breathing, night and morning, for gradually increasing periods are useful ; chest expansion exercises may be prescribed later.

In cases of tuberculous glands, joints, bone disease, vesical ulcers, and discharging sinuses after operations on the kidney or lung, the treatment is the same as previously outlined, but any enclosed pus must be evacuated.

In tuberculous patients who are subject to asthma, these insufflations may sometimes lead to a temporary tightness on the chest or to an asthmatic attack. In such cases it is often beneficial to apply adrenalin ointment or the galvano-cautery to the middle turbinates in order to reduce turgescence.

Whilst it is possible by nasal insufflations to stimulate antibody production, and thereby bring about recovery from tuberculosis, it is essential for the maintenance of immunity that any anatomical defects in the nose should be rectified, so that mouth breathing shall not be practised and that all inspired air shall pass along the upper regions of the nose.

[It is obvious that the treatment should be carried out under the direction of a medical man, with special attention to aseptic methods, so that the possibility of introducing secondary infections may be obviated.]

* Constable, London, 1923.

The Paget T. B. E. Insufflation Outfit containing 2 insufflation tubes, 1 rubber pneumatic bulb and 3 tubes of T. B. E. tablets (1 of 1/1000 mgm., 1 of 1/100 mgm., and 1 of 1 mgm.), is supplied by

Parke, Davis & Co., 50, Beak Street, Regent Street, London, W. 1.

Valentine's Meat-Juice

In **Diarrhoea, Dysentery** and **Cholera Infantum,** in the **Wasting** and **Febrile Diseases** of **Children,** and in the treatment of **Weak Babies,** the **Ease** of **Assimilation** and **Power** of **Valentine's Meat-Juice** to **Restore** and **Strengthen** has been demonstrated in Hospitals for Children.

Diseases of Children.

Thos. N. Vincent, M. D., *Visiting Physician St. Ann's Infant Asylum, Washington, D. C.:* "I have used Valentine's Meat-Juice in St. Ann's Infant Asylum, in the treatment of cases of Diarrhoea, incident to Teething in infants of delicate constitutions, and find it in every way satisfactory. It is easily assimilated, attended with no untoward symptoms and agrees in cases where other foods fail and when milk, prepared in any way used at present, also failed. I can testify also to its usefulness as a nutrient in Scarlet Fever and Measles."

W. B. Scranton, M. D., *Medical Superintendent Korean Mission Methodist Episcopal Church, Seoul, Korea:* "A most excellent use I frequently put Valentine's Meat-Juice to is tiding Babies through Cholera Morbus and the Wasting diseases incident to Summer and Inanition. It acts at once, and many a crisis has been passed safely by my patients through the agency of Valentine's Meat-Juice. It has also been of great value in my practice in the Far East in the treatment of that form of Summer Diarrhœa known as Sprue, where it tides the patients over until they can get to a better climate, and the change of climate rectifies the rest."

Dr. Raphael Raimondi, *Consulting Physician to the Montmartre Nurseries, Paris, France:* "I use Valentine's Meat-Juice with Nurslings eighteen months to two years old. These very weak Babies derive great benefit from the use of this tonic preparation. I give it to Debilitated Infants, after they are eighteen months old, in doses of one teaspoonful in thirty gramms of boiled water twice a day, and to be continued for a month."

VALENTINE'S PREPARATION
NUTRIO PERME
MEAT JUICE.
The result of an original Process of Preparing Meat, and extracting its Juice, by which the elements of nutrition are obtained in a state, ready for immediate absorption.
DIRECTIONS—Dissolve one teaspoonful of the Preparation in two or three tablespoonfuls of cold or warm water. The use of boiling water changes the character of the preparation.

Antikamnia Tablets

Strongly Recommended in:

INFLUENZA & LA GRIPPE

For the headache, pain, and general soreness give a five-grain Antikamnia Tablet crushed with a little water; if the pain is very severe two tablets should be given. Repeat every 2 or 3 hours as required. One single ten-grain dose is often followed by complete relief.

NEURALGIA

In the Treatment of Neuralgia and Myalgic Pains Antikamnia Tablets are not only palliative, but, along with other measures, assist in ultimate cures; they also have a field of use in Rheumatic and Gouty Affections. In Neurasthenia, Hysteria, and Migraine they are a valuable adjuvant to the other recognised therapeutic measures.

LARYNGEAL COUGH

Frequently remains after an attack of Influenza, and has been found stubborn to yield to treatment. There is an irritation of the larynx, huskiness, and a dry and wheezing cough, usually worse at night. The prolonged and intense paroxysms of coughing are controlled by **ANTIKAMNIA & CODEINE TABLETS**, and with the cessation of the coughing the laryngeal irritation subsides.

Antikamnia Tablets are the least depressing of all the drugs that can exercise so extensive a control of pain, and also least disturbing to the digestive and other organic functions.

Analgesic. Antipyretic. Anodyne.

Antikamnia Preparations in 1-oz. packages only.

GOLD MEDAL, INTERNATIONAL CONGRESS OF MEDICINE, LONDON, 1913.

MIST. DAMIANÆ CO. (HEWLETT'S)

MIST. DAMIANÆ CO. (**Hewlett's**) will be found to possess all the properties of Damiana, viz.:—Its alterative effects on the alimentary canal and tonic action upon the brain and nervous system generally. It is a well-known fact that exhaustion of the organs and tissues, neurasthenia, and premature decay, are far more prevalent at the present day than ever before. The causes are numerous and complex, but, perhaps the principal reason is that multitudes have to toil harder with their brains than any previous race. The resulting cerebral anæmia is, therefore, one of the most general complaints in modern life. Not only is it found amongst the professional literary men, but busy merchants and overworked scholars are equally the subjects of enfeebled nerve power and deficient vitality.

In all these various forms of loss of nerve power MIST. DAMIANÆ Co. (Hewlett's) is a powerful remedy, relieving the exhaustion and conferring renewed capacity for mental and physical endurance.

As a nerve tonic and brain stimulant it is unequalled, and its invigorating properties will be found invaluable in many diseases where there is great depression and exhaustion. In paraplegia, hemiplegia, and partial paralysis, it is particularly indicated, and may be suitably and satisfactorily employed wherever a powerful nerve stimulant and restorative are required.

Dose—One or Two Drachms in Water.

MEDICAL OPINIONS.

"I have tried your Mist. Damianæ Co. considerably in the dyspepsia of commencing phthisis, and can very strongly recommend its use in those cases. **It soothes the stomach wonderfully, and enables the patient to take more food whilst acting as a powerful stimulant in relieving exhaustion."**—Yours faithfully, W. H. B——, B.A. (Cantab.), M.R.C.S., L.S.A.

THE MEDICAL ANNUAL.—"Damianæ is not used so frequently in this country as in America, where its value as a tonic for Neurasthenia is well known. Messrs. HEWLETT & SON put up a very excellent preparation of this drug, combined with Nux Vomica and simple aromatics and bitters, which is valuable for dispensing, and yields very satisfactory results in treatment."—1898.

Dr. M——, R.N., writes:— " Farnham (Hants.), Sept., 1903.
"I have frequently prescribed your Mist. Damianæ Co. and proved it efficient in treating Neurasthenia."

Packed in 10-oz., 22-oz., 40-oz., and 90-oz. Bottles.

C. J. HEWLETT & SON, LTD., 35 to 42, Charlotte Street, LONDON, E.C.2.

BISMOLAN

SUPPOSITORIES & OINTMENT for the Treatment of Hemorrhoids

Bismolan preparations contain bismuth-oxychloride, which is disinfectant, and prevents the passage of infectious germs into the veins. Besides, they contain mixtures which are cooling, control pain and itching, and contract the mucous membrane and blood-vessels.

The formula is printed on each box.

SECWAY

PURE SWEET WHEY IN POWDER FORM

Composition: LANCET Analysis

Whey Protein (Chiefly Soluble Lactalbumen)	- -	14·25
Milk Sugar	- -	74·45
Milk Salts	- -	9·80
Fat	- - - -	0·27
Moisture	- - -	1·20

Secway is dried whey, made from the purest Cheshire dairy milk by a process which ensures instant solution in water. It is highly nourishing and readily assimilable, and forms an ideal basis of feeding in extreme gastric conditions, such as Enteritis, Typhoid, Dysentery, etc., being retained when all other nourishment is rejected.

In sealed 8-oz. tins at 1/9 each

FOR INTERNAL TREATMENT OF GONORRHŒA, URETHRITIS AND OTHER AFFECTIONS OF THE GENITO-URINARY TRACT.

Santal Midy Capsules have been prescribed with uniform success for over 30 years. Distilled from carefully selected Mysore Sandal Wood, the oil is bland and remarkably

FREE FROM THE IRRITANT AND NAUSEATING EFFECTS

which are provoked by many reparations.

SANTAL MIDY

There is a marked absence of Gastric and other disturbances, diarrhœa and skin eruptions. Its mild chemotactic properties permit its administration in relatively large doses without fear of too violent reaction or intolerance.

SANTAL MIDY CAPSULES may be prescribed and relied upon in all stages of Gonorrhœa and in other forms of Urethritis and affections of the Genito-urinary Tract. The capsules contain 5 drops, and usually 10 to 12 are given daily in divided doses.

Prepared in the Laboratoire de Pharmacologie Générale, 8, Rue Vivienne, Paris, and sold by most Chemists and wholesale Druggists throughout the world.

U.K. Agents: WILCOX, JOZEAU & CO., 15, Gt. St. Andrew St., W.C.2.

PULMO
(BAILLY)

A Marked Advance in Scientific Pharmacy

Ensures the remineralisation of the Organism and the Encapsulation of Bacillary Lesions

PULMO, unlike the old-fashioned pharmaceutical preparations of phosphates and calcium, which were not assimilated, but passed through the body unchanged, contains these mineral substances in the ionized state (introduced by Prof. Stephane Leduc and Dr. A. Bouchet). Consequently they are eminently active, and ready to form stable combinations with the constituent elements of the organism.

PULMO is indicated in common colds, Catarrh, Laryngitis, Tracheitis, Bronchitis, Asthma, Pneumonia, and all Pre-Tubercular states.

PULMO has a world-wide reputation among Medical men, as a most efficient combination of those principles which act specifically on the diseased tissues and morbid secretions of the Respiratory Tract.

REED & CARNRICK'S

PEPTENZYME

The Nucleo-Enzymes of the Salivary, Peptic, Pancreatic, Spleen, and Intestinal Glands.

REINFORCES and supplements the action of the different digestive enzymes, in converting starches into sugars, proteins into peptones, fats into glycerine and fatty acids, and finally the complex sugars, proteoses and peptones into simpler and more readily assimilable products.

Through its content of substances, which in the living body produce reflex stimulation of the local blood supply, more nourishment is brought to these secreting gland cells. More nourishment means greater functional power, and the building up of cell substance and vitality. It is this effect on the nutrition of the digestive gland cells that largely accounts for the permanent benefits that so notably attend the use of Peptenzyme.

PURE TABLE WATER

Every bottle direct from the spring at Glinton, Near Peterborough

ON Dec. 16th, 1922, the *Lancet* stated that HYDROX Natural Soda Water was free from all organic impurity, pleasing to the eye and agreeable to the taste. Doctors therefore have the utmost confidence in prescribing this excellent British Table Water, which is perfectly miscible with milk, wines or spirits.

This was the analysis expressed as parts per 100,000:—

Total Solid Matter	74.40
Chlorine (Cl)	17.30
Sulphates (SO_4)	6.96
Lime (CaO)	6.44
Magnesia (MgO)	2.00
Soda (Na_2O)	30.00
Free Ammonia, Albuminoid Ammonia	Negligible traces
Oxygen absorbed (3 hours at 80°F.)	0.048

It is extremely soft and does not re-act on the stomach, while, as the analysis shows, it possesses certain curative properties especially suitable for persons suffering from gout and rheumatism. Send an order to your chemist or stores for

ROBERTS & CO., 76, New Bond St., LONDON, W.

THE SOCIETY OF MEMBERS OF THE ROYAL COLLEGE OF SURGEONS OF ENGLAND

Since 1894 this Society has been heartily supported by those Members desirous of recovering their ancient rights and obtaining some representation of the general practitioner on the Council of the College, which (at present) consists only of Fellows, who are consulting surgeons.

Such representatives could voice in the Council Chamber the needs of the 16,157 Members, whose interests require a special knowledge, without which they are likely to be neglected or ignored. Last year the Members contributed £15,381 to the funds of the College, compared with £5,156 from the Fellows.

New and more effective methods are now being inaugurated by the Society, which appeals to all Members and to those Fellows with generous and progressive instincts (especially those in general practice) asking them to give the Society their support and become annual subscribers of half-a-crown. **The work done by the Society will depend on the funds at its disposal.**

Please write for fuller information to the Honorary Secretary, Dr. S. C. Lawrence, 106, Richmond Park-road, Bournemouth.

the Hospital;
H. R. JEREMY, F.R.C.S.,
Assistant Surgeon to the Ophthalmic Dept.
of the Hospital.

DISEASES OF THE SKIN.
BY
J. H. SEQUEIRA, M.D., F.R.C.P., F.R.C.S.,
Physician to the Skin Dept. of the Hospital.

An Examination will be held at the end of the Course and Certificates of Efficiency awarded to those who reach the required Standard.

A limited number will be admitted to the Course, which will extend over three months. Fee 15 guineas. Further particulars may be obtained on application to the Dean, Professor WILLIAM WRIGHT, M.B., D.Sc., F.R.C.S., London Hospital Medical College, Mile End, E. 1.

THE CHARTERED SOCIETY OF MASSAGE AND MEDICAL GYMNASTICS

Examinations will be held during 1923 in MASSAGE, MEDICAL GYMNASTICS, and MEDICAL ELECTRICITY, and for TEACHERS' CERTIFICATES. TRAINING COURSES, 12-15 months; TEACHERS, 2 years.

For the benefit of Masseuses and Masseurs holding Certificates other than I.S.T.M. prior to June 9th, 1920, TEST EXAMINATIONS in MASSAGE and other subjects are arranged. Conditions of entry supplied to applicants.

Examinations are held in London, and also in Dublin, Manchester, Glasgow or Edinburgh, and Bristol, when there are sufficient (30) entries.

The Society is approved by the Medical Profession, and its certificate-holders work only under medical direction. The Certificate of the Society is a qualification accepted by the Admiralty, War Office, Ministry of Pensions, and the British Red Cross Society.

All enquiries for Masseuses and Masseurs in London and the Provinces will receive prompt attention on application to the Secretary, C.S.M.M.G., 157, GREAT PORTLAND STREET, W. 1. *Telephone: Langham* 1893.

The Faculty embraces 19 Chairs and 65 Lectureships, and attached to these Chairs there are about 40 Assistants and Demonstrators. Instruction is given in all the main branches of Medical Science, viz. :—

PROFESSORS.

Chemistry—George Barger, D.Sc., F.R.S.
Zoology—J. Cossar Ewart, M.D., F.R.S., J. H. Ashworth, D.Sc., F.R.S.
Botany—Wm. Wright Smith, M.A., F.R.S.
Anatomy—Arthur Robinson, M.D.,
Physiology—Sir E. Sharpey Schafer, LL.D., F.R.S.
Materia Medica—A. R. Cushny, M.D., LL.D., F.R.S.
Pathology—J. Lorrain Smith, M.D., F.R.S.
Bacteriology—(Vacant.)
Forensic Medicine—Harvey Littlejohn, M.B., B.Sc.
Public Health—C. Hunter Stewart, M.B., D.Sc.
Medicine—George Lovell Gulland, C.M.G., M.D.
Surgery—Alexis Thomson, C.M.G., M.D., B.Sc.
Midwifery and **Gynæcology**—Benjamin P. Watson, M.D.
Clinical Surgery—Sir H. J. Stiles, K.B.E., M.B., C.M.
Clinical Medicine—Edwin Bramwell, M.D., George Lovell Gulland, M.D., J. C. Meakins, M.D.
Tuberculosis—Sir Robert W. Philip, M.D.
Therapeutics—J. C. Meakins, M.D.
Psychiatry—George M. Robertson, M.D.

UNIVERSITY LECTURERS.

Clinical Surgery — Alexis Thomson, C.M.G., M.D., C.M., Sir David Wallace, C.M.G., M.B., C.M., Alexander Miles, M.D., C.M., J. W. Dowden, M.B., C.M., A. A. Scot Skirving, C.M.G., M.B., C.M., G. L. Chiene, M.B., C.M.
Clinical Medicine—R. A. Fleming, M.D., D. Chalmers Watson, M.D., Edwin Matthew, M.D., W. T. Ritchie, M.D.
Clinical Gynæcology—J. Haig Ferguson, M.D., William Fordyce, M.D.
Diseases of the Eye—J. V. Paterson, M.B., C.M., A. H. H. Sinclair, M.D.
Clinical Instruction in Diseases of Children—J. Stewart Fowler, M.D., John Fraser, M.D., Charles M'Neil, M.D., and N. S. Carmichael, M.B., Ch.B.
Anatomy—E. B. Jamieson, M.D.,
Applied Anatomy—F. E. Jardine, M.B.
Histology—R. K. S. Lim, M.B., Ph.D.
Physiological Chemistry—W. W. Taylor, D.Sc.
Experimental Physiology—May L. Walker, M.A., B.Sc., M.B.
Physiology of the Nervous System—A. Ninian Bruce, M.D., D.Sc.
Experimental Pharmacology—W. C. Sillar, M.D., B.Sc.
Pathology (Practical)—F. E. Reynolds, M.B.
Morbid Anatomy—W. A. Alexander, M.B.
Physics—G. A. Carse, M.A., D.Sc.
Diseases of the Larynx, Ear, and Nose—A. Logan Turner, M.D., John S. Fraser, M.B., J. D. Lithgow, M.B.
Tropical Diseases—D. G. Marshall (Lt.-Col., I.M.S.).
Medical Entomology and Parasitology — J. H. Ashworth, D.Sc., F.R.S., and W. S. Patton (Major, I.M.S.).

Diseases of the Skin—Sir Norman Walker, M.D., Frederick Gardiner, M.D.
Clinical Instruction in Infectious Fevers—Alexander James, M.D., Claude B. Ker, M.D.
History of Medicine—J. D. Comrie, M.A., B.Sc., M.D.
Neurology—
Surgical Pathology—J. M. Graham, M.B., Ch.M.
Practical Anæsthetics—J. Stuart Ross, M.B., Ch.B., *Demonstrator.*
Venereal Diseases—David Lees, M.B.
Psychology—J. Drever, M.A., B.Sc., D.Phil.

Practical instruction is afforded, under the superintendence of the Professors, in Laboratories with the necessary appliances, and in Tutorial and Practical Classes connected with the above Chairs, and opportunities are afforded to Students to extend their practical knowledge and engage in original research.

Opportunities for Hospital Practice are afforded at the Royal Infirmary, the Hospital for Sick Children, Maternity Hospital, the City Fever Hospital and the Asylum for the Insane. Upwards of 2760 beds are available for the Clinical Instruction of Students of the University.

Four Degrees in Medicine and Surgery are conferred by the University of Edinburgh, viz., Bachelor of Medicine (M.B)., Bachelor of Surgery (Ch.B.), Doctor of Medicine (M.D.), and Master of Surgery (Ch.M.)

The minimum Class Fees for M.B. and Ch.B., including Hospital Fee (£12), amount to about £200, and the Matriculation and Examination Fees to £45 3s. An additional fee of £21 is payable by those who proceed to M.D., and £21 by those who proceed to Ch.M.

The annual value of the Bursaries, Prizes, Scholarships, and Fellowships in the Faculty of Medicine amounts to about £3600, and that of the other Bursaries, &c., tenable by students of Medicine, amounts to about £1820.

UNIVERSITY OF EDINBURGH—*continued.*

POST-GRADUATE INSTRUCTION.—Courses of instruction are given for the Degrees of B.Sc. and D.Sc. in Public Health and for the University Diplomas in Public Health, Tropical Medicine and Hygiene, and Psychiatry. These Diplomas are open to approved registered practitioners as well as to graduates in Medicine and Surgery of the University. The University also takes part in the Courses given under the auspices of the Edinburgh Post-Graduate Courses in Medicine. In the departments of the Faculty of Medicine provision is made for research by students of graduate standing. In the University laboratories facilities will be provided for candidates for the Degree of Ph.D. whose applications to engage in research have been accepted by the Senatus.

A Syllabus and further information as to Matriculation, the Curricula of Study for Degrees, &c., may be obtained from the Dean of the Faculty of Medicine; and for Degrees in the Faculties of Arts, Science, Divinity, Law, and Music from the Deans of these Faculties, or from the Secretary; and full details are given in the University Calendar, published by James Thin, 55, South Bridge, Edinburgh. Price by post, 6s.

By Authority of the Senatus,
1923. WILLIAM WILSON, Secretary.

INCORPORATED 1505.

KALMERID Catgut
(Germicidal)
is Reliable

as to compatibility with the tissues, and as to absorbability, tensile strength, sizes, and sterility

KALMERID CATGUT is an improved germicidal suture superseding iodized catgut. It is not only sterile, but, being impregnated with potassium-mercuric-iodide—a double iodine compound—the sutures exert a local bactericidal action in the tissues

Sterilized by Heat After Closure of the Tubes

The heat sterilizing procedure consists in submerging the tubes, after they have been sealed, in a bath of cumol, and there exposing them for five hours to the rigourous temperature of 165°C (329°F) It is obvious that sterility is quite assured.

KALMERID CATGUT
is made in two varieties—
the Boilable and the Non-Boilable

The Boilable Grade is sterilized by heat, after the tubes are hermetically sealed, in the manner described. The tubes may be boiled as often as desired for the purpose of sterilizing their exterior preliminary to use. They even may be autoclaved up to 30 pounds pressure without affecting their physical integrity in the slightest

The Non-Boilable Grade possesses extreme flexibility—a characteristic sometimes desired by surgeons accustomed to the use of iodized sutures

Varieties of The Boilable Grade		Varieties of Non-Boilable Grade	
No. 1205	Plain Catgut	No. 1405	Plain Catgut
No. 1225	10-Day Chromic Catgut	No. 1425	10-Day Chromic Catgut
No. 1245	20-Day Chromic Catgut	No. 1445	20-Day Chromic Catgut
No. 1285	40-Day Chromic Catgut	No. 1485	40-Day Chromic Catgut

All Varieties are made in Sizes 000-00-0-1-2-3-4
Each Tube Contains Approximately 60 inches of Catgut

Complete literature will be sent upon request, including reprints of several original articles reporting studies relative to sutures

Price at London, all Tariffs Paid:
Per package containing 12 tubes of one kind and size......... 12 s.
A wholesale discount of 25% is allowed hospitals and surgeons on 12 packages or [illegible] (£5-8s. net per gross of tubes)
Carried in stock by C.F. Thackray, Great George Street, Leeds; 119, High Holborn, London, W.C.1
obtainable also through any of the other responsible dealers,
or, carriage and tariffs paid, direct of the manufacturer

"Strong evidence exists that the respiratory pigment hæmoglobin is derived both phylogenetically and physiologically from chlorophyll."

J. F. FULTON
(BERMUDA RESEARCH).
QUARTERLY JOURNAL MICROSCOPICAL SCIENCE,
Vol. 66, Part II.

"There is no doubt that chlorophyll is related to the hæmoglobin of man."

(Sir A. E. SHIPLEY, F.R.S.)
ROYAL INSTITUTION,
LECTURE 27/2/23.

Prof. E. Buergi, of the University, Berne, has isolated pure chlorophyll in an extraction called PHYLLOSAN. The mass of medical evidence and clinical reports on Phyllosan in cases of Anæmia, Chlorosis, Wasting Diseases, &c., would qualify his theory beyond a doubt.

Literature, Free Samples, Copies of Clinical Reports sent on application.

CHLOROPHYL & CHEMICAL CORP., LTD.
26, Coventry Street - - LONDON, W. 1.

"Even the most detached and cynical observer of human failings must glow with a sense of worship when he perceives this relationship."
